Grammar is the system that specifies how vocabulary units can be combined into words, phrases, and sentences, and how the meaning of a combination can be determined by the meanings of the units and the way they are arranged. It allows us to distinguish, for example, between *Man bites dog* and *Dog bites man*, using the positions of the words *man* and *dog* with respect to *bites*. Because grammar is based on a set of rules for assembling words into new combinations, rather than on the storage and recall of fixed word sequences, the number of sentences a language speaker can produce and understand is vast. The number of possibilities grows exponentially with the length of the sentence; there are on the order of 10_{20} grammatically meaningful sentences of 20 words or fewer. Indeed, the number of possible sentences is in principle infinite, because one can embed one sentence inside another without limit: *I think that he thinks that she thinks that...*

Grammar has three main components: morphology, syntax, and phonology. *Morphology* refers to the rules for combining words and affixes into larger words, as in *fax* + *able* + *ity* or *bite* + *s*. In many languages morphology plays a crucial role in conveying who did what to whom. Nouns are marked with suffixes that help indicate whether the noun is the agent, the affected party, or some other kind of participant in the event or state, and verbs are marked with suffixes that pin down various properties of those participants (such as person, number, and gender). Old English relied heavily on these devices, and modern English has vestiges of them in pronoun case (*I* versus *me*, *he* versus *him*) and subject-verb agreement (*He dawdles* versus *They dawdle*).

Syntax consists of rules for combining words into phrases and sentences and determining relations among words. These rules do not simply order words in a linear string. At heart, syntax involves three principles. First, sequences of words are grouped into phrases, which are grouped into larger phrases, and so on, defining a tree-like phrase structure. For example, in *Animal Crackers* Groucho Marx said, "I once shot an elephant in my pajamas. How he got into my pajamas I'll never know." The joke stems from the fact that two phrase structures are possible for the same sequence of words: "[I shot] [an elephant] [in my pajamas]," and "[I shot] [an elephant in my pajamas]."

Second, the verb determines how the meanings of the words in a phrase structure are to be integrated into a cohesive proposition. A person's "mental dictionary entry" for a word includes not just its sound, meaning, and grammatical category (noun, verb, adjective, preposition) but also a grammatical subcategory. Familiar examples of subcategories for verbs are those for transitive and intransitive verbs. A *transitive verb* requires an object

P.1171

(eg, we say *Maria devoured the pizza*, never just *Maria devoured*), while an *intransitive verb* does not have an object (eg, we say *Maria dined*, not *Maria dined the pizza*). The subcategory of a verb specifies the semantic roles of its *arguments*, the different participants in the action or state expressed by the verb. For example, in the sentences *Man fears dog* and *Man frightens dog*, *man* has a different role despite the fact that the word occupies the same position

in both phrases. The word *fear* specifies “the subject is the experiencer, the object is the cause,” whereas *frighten* specifies “the subject is the cause, the object is the experiencer.” To understand either of these sentences, one must distinguish between the subject and the object; they can be identified by their positions in phrase structure, their case endings, or both.

The third syntactic principle is that two phrases in a sentence are sometimes linked so that they refer to the same entity in the world, a phenomenon called *anaphora*. For example, in *Sheila washed herself* the words *Sheila* and *herself* are understood to refer to the same person. Sometimes the process of anaphora links a word to a structural gap later in the sentence that provides a clue to the role of the word in the sentence. In the sentence *Which man did the dog bite* —, the semantic role of *which man* (the man who was bitten) is determined not by the position of that phrase at the beginning of the sentence but by the empty object position after the word *bite*. That is, the position for the object is left empty and is not expressed overtly in the speaker's utterance. This phenomenon motivated Noam Chomsky to distinguish between the deep structure and the surface structure of a sentence. In the *deep structure* every phrase is in its proper position (for example, *which man* would follow *bite*). However, a movement rule or transformation can move a phrase to another position (such as the beginning of the sentence), leaving behind a gap (or *trace*). The resulting structure of the sentence is called the *surface structure*.

The third subsystem of grammar, *phonology*, consists of rules combining sounds into a consistent pattern in the language. For example, we recognize that *blicket* may be an English word, whereas *ngagat* probably is not. But unlike syntax and morphology, phonology does not assign a meaning to the elements it combines. Sound elements of phonemes, such as *t* and *i*, and their articulatory components, such as voicing and use of the tongue tip, do not themselves have meanings, nor does their arrangement correspond to some meaningful relation among entities. (There is nothing in the ordering of *d*, *o*, and *g* that predicts how the meaning of *dog* differs from the meaning of *god*.) The rules of phonology, then, are merely a way of taking a small set of basic articulatory gestures and using them to form a vast set of possible words, each with an arbitrary meaning that must be memorized. Phonology also embraces *prosody*: patterns of intonation, stress, and timing that span entire phrases and sentences. Prosody can have a grammatical role—for example, in distinguishing words (*blackboard* versus *black board*)—as well as a broader communicative function, differentiating questions from statements, supplying emphasis, indicating sarcasm, and expressing emotion.

Using grammar and lexicon alone does not allow one to produce or comprehend a sentence. Grammar and lexicon are merely codes, or protocols, that establish a relationship between meanings and signals for a given language. To produce a sentence one must choose words and use grammatical rules to encode ideas and intentions (that is, the message) and generate a set of articulatory commands to the motor system. To comprehend a sentence one must coordinate the sensory information that comes in through the auditory system (or the visual system in signing and reading) with the grammar and lexicon and send information about the resulting interpretation (the message) to the systems underlying memory and reasoning. Using language, then, requires complex patterns of information flow involving many parts of the brain.

Complex Language Develops Spontaneously in Children

According to Darwin, “Man has an instinctive tendency to speak, as we see in the babble of our young children; while no child has an instinctive tendency to brew, bake, or write.” In the first year of life children work on sounds. They begin to make language-like sounds at 5-7 months, babble in well-formed syllables at 7-8 months, and gibber in sentence-like streams by the first year. In their first few months, they can discriminate speech sounds, including ones that are not used in their parents' language and that their parents do not normally discriminate (for example, Japanese babies can discriminate *r* and *l*). By 10 months they discriminate phonemes much as their parents do. This tuning of speech perception to the specific ambient language precedes the first words, so it must be based on the infant performing sophisticated acoustic analyses, rather than on the infant correlating the sounds of words with their meanings.

A child's first words are spoken around the time of his or her first birthday, and the rate of word learning increases suddenly around age 18 months, which is also the age at which children first string words into combinations such as *More outside* and *Allgone doggie*. Children at age 2 begin to speak in rich phrase structures and

P.1172

master the grammatical vocabulary of their language (articles, prepositions, etc). By age 3, children use grammatical words correctly most of the time, use most of the constructions of the spoken language appropriately, and in general become fluent and expressive conversational partners. Although children make many errors, their errors occur in a minority of the words they use and are highly systematic. Indeed, this fact confirms what we might have guessed from the fact that children are so fluent and creative: children must be engaging in sophisticated grammatical analysis of their parents' speech rather than merely imitating them.

Take, for example, this error of a 3-year-old: *Mommy, why did he dis it appear?* First, it shows that children do not merely record stretches of sound but are hyperalert for word boundaries. This child misanalyzed *disappear* as *dis appear*. Second, this error shows that children work to classify words in grammatical categories. The child's newly extracted *appear* is being used not as the verb an adult uses but as a unit of speech that the child has hypothesized from the context, namely, a particle (examples of particles are the second words in *blow away* and *take apart*). Third, it shows how children look for grammatical subcategories that determine the interaction between words and grammar. The child creatively converted an intransitive verb meaning “vanish” to a transitive verb meaning “cause to vanish,” in conformity with a widespread pattern in English grammar: *The ice melted/She melted the ice; The ball bounced/She bounced the ball*, and so on.

Languages Are Learned and the Capacity to Learn Language Is Innate

Language, like other cognitive abilities, cannot be attributed entirely to either innate structure or learning. Clearly, learning plays a crucial role: any child will acquire any language he or she is exposed to. Likewise, “wild children” who are abandoned by parents to survive in forests, or who are raised in silent environments by deranged parents, are always mute. But learning cannot happen without some innate mechanism that does the learning, and other species exposed to the same input as a child fail to learn at all. In 1959 Chomsky proposed a then-revolutionary hypothesis that children possess innate neural circuitry specifically dedicated to the acquisition of language. The hypothesis is still controversial; some psychologists and linguists believe that the innate capacity for language is merely a general capacity to learn patterns, not a specific system for language, and that the brain areas subserving these skills have no properties that are tailored specifically to the design of language.

Several kinds of evidence have been adduced to support Chomsky's hypothesis. First, there are the gross facts of the distribution of language across the species. People in technologically primitive cultures, helpless 3-year-olds, and poorly educated adults in our culture all master complex grammar when they first acquire language, and they do so without special training sequences or feedback. Indeed, when children in a social environment are deprived of a bona fide language, they create one of their own; this is how the sign languages of the deaf arise. Similarly, in the eighteenth and nineteenth centuries, slave children living on plantations and children in other mixed-culture societies who were exposed to crude *pidgin* languages (choppy strings of words) used by their parents developed full-fledged languages, called *creoles*, from the pidgin languages. In all these cases the languages children master or create follow the universal design of language described earlier in this chapter.

In addition, language and more general intelligence are dissociated from one another in several kinds of pathological conditions. Children with a heritable syndrome called *specific language impairment* can have high intelligence, intact hearing, and normal social skills but have long-lasting difficulty in speaking and understanding according to the grammatical rules of their language. Conversely, children with certain kinds of mental retardation can express their confabulated or childlike thoughts in fluent, perfectly grammatical language and score at normal levels on tests of comprehension of complex sentences. These dissociations, in which complex language abilities are preserved despite compromised intelligence, can appear in people who have hydrocephalus caused by spina bifida and in people with Williams syndrome, a form of retardation associated with a defective stretch of chromosome 7.

Finally, grammar has a partly quirky design that cuts across the categories underlying concepts and reasoning. Consider the statements *It is raining* and *Pat*

is running. Both "it" and "Pat" have the same grammatical function; both words serve as subjects of the sentence and both can be inverted with the verb to form a question (*Is it raining? Is Pat running?*) despite the fact that "it" is a grammatical placeholder without cognitive content. Though the sentence *The child seems to be sleepy* can be shortened to *The child seems sleepy*, the nearly identical sentence *The child seems to be sleeping* cannot be shortened to *The child seems sleeping*. Subtleties such as these, which emerge in all speakers without specially tailored training sequences or systematic feedback, are consequences of the design of grammar; they cannot be predicted from principles governing what makes sense or what is easy or difficult to understand.

P.1173

In sum, children seem to acquire language using abilities that are more specific than general intelligence but not so specific as the capacity to speak a given language—English, Japanese, and so on. What, then, is innate? Presumably, it is some kind of neural system that analyzes communicative signals from other people, not as arbitrary sequences of sound or behavior but according to the design of language. By following this design a child learns a lexicon of bidirectional arbitrary pairings of sound and meaning and several kinds of grammatical rules. One kind assembles phonological elements into words; other kinds assemble words into bigger words, phrases, and sentences according to the principles of phrase structure, grammatical categories and subcategories, case and agreement, anaphora, long-distance dependencies, and movement transformations. Presumably all these abilities come from adaptations of the human brain that arose in the course of human evolution.

Other Animals Appear to Lack Homologs of Human Language, but Language May Nonetheless Have Evolved by Darwinian Natural Selection

One might think that if language evolved by gradual Darwinian natural selection it must have a precursor in other animals. But the natural communication systems of nonhuman animals are strikingly unlike human language. They are based on one of three designs: a finite repertoire of calls (eg, one to warn of predators, one to announce a claim to territory), a continuous analog signal that registers the magnitude of some condition (eg, the distance a bee dances signals the distance of a food source), or sequences of randomly ordered responses that serve as variations on a theme (as in birdsong). There is no hint of the discrete, infinite combinatorial system of meaningful elements seen in human language.

Some animals can be trained to mimic certain aspects of human language in artificial settings. In several famous and controversial demonstrations, chimpanzees and gorillas have been taught to use some hand signs based on American Sign Language (though never its grammar), manipulate colored switches or tokens, and carry out some simple spoken commands. Parrots and dolphins have also learned to recognize or produce ordered sequences of sounds or other signals. Such studies have taught us much about the cognitive categories of nonhuman species, but the relevance of these animal behaviors to human language is questionable.

It is not a matter of whether one wants to call the trained artificial systems "language." This is not a scientific question, but a matter of definition—how far are we willing to stretch the meaning of the word *language*? The scientific question, and the only one relevant to whether these trained behaviors can serve as an animal model for language, is whether the abilities are *homologous* to human language—whether the two cognitive systems show the same basic organization owing to descent from a single system in a common ancestor. For example, biologists do not debate whether the wing-like structures of gliding rodents (flying squirrels) may be called "genuine wings" or something else (an uninformative question of definition). These structures are not homologous to the wings of bats because they have a different anatomical plan reflecting a different evolutionary history. Bat wings are modifications of the hands of a common mammalian ancestor; the wings of a flying squirrel are modifications of its rib cage. The two structures are merely similar in function, or *analogous*, but not homologous.

Though artificial signaling systems taught to animals have some analogies to human language (eg, they are used in communication and sometimes involve combining basic signals), it seems unlikely that they are homologous. Chimpanzees require extensive teaching contrived by another species (humans) to acquire rudimentary abilities, mostly limited to a small number of signs, strung together in repetitive, quasirandom sequences, used with the intent of requesting food or tickling. The core design of human language—particularly the formation of words, phrases, and sentences according to a single plan that supports both production and comprehension—fails to emerge as the chimps interact with each other and, as far as we know, it cannot be taught to them.

All this contrasts sharply with human children, who learn thousands of words spontaneously; combine them in novel structured sequences in which every word has a role; respect the word order, case marking, and agreement of the adult language; use sentences for a variety of nonutilitarian purposes, such as commenting on interesting objects; and creatively interpret the grammatical complexity of the input they receive (reflected in their systematic errors or in their creation of novel sign languages and creoles).

Nevertheless, this lack of homology does not cast doubt on a Darwinian, gradualist account of language evolution. Humans did not evolve directly from chimpanzees. Both evolved from a common ancestor, probably around 6-8 million years ago. This time span leaves about 300,000 generations in which language could have evolved gradually in the lineage leading to humans after it split off from the lineage leading to chimpanzees. Presumably language evolved in the human lineage because of two related adaptations in our ancestors:

P.1174

They developed technology to exploit the local environment in their lifetimes and were involved in extensive cooperation. These preexisting features of the hominid lifestyle may have set the stage for language, because language would have allowed evolving hominids to benefit by sharing hard-won knowledge with their kin and exchanging it with their neighbors.

Figure 59-1 Language-related areas in the human brain.

A. A highly simplified view of the primary language areas of the brain are indicated in this lateral view of the exterior surface of the left hemisphere. Broca's area (**B**) is adjacent to the region of the motor cortex (pre-central gyrus) that controls the movements of facial expression, articulation, and phonation. Wernicke's area (**W**) lies in the posterior superior temporal lobe near the primary auditory cortex (superior temporal gyrus). Wernicke's and Broca's areas are joined by a bidirectional pathway, the arcuate fasciculus (**brown arrow**). These regions are part of a complex network of areas that all contribute to normal language processing.

B. Modern and more elaborate view of the language areas in a lateral view of the left hemisphere. These languages area contain three functional language systems: the implementation system, the mediational system, and the conceptual system. Two of these are illustrated here. The *implementation system* is made up of several regions located around the left sylvian fissure. It includes the classical language areas (**B** = Broca's area; **W** = Wernicke's area) and the adjoining supramarginal gyrus (**Sm**), angular gyrus (**AG**), auditory cortex (**A**), motor cortex (**M**), and somatosensory cortex (**Ss**). The posterior and anterior components of the implementation system, respectively Wernicke's area and Broca's area, are interconnected by the arcuate fasciculus. The *mediational system* surrounds the implementation system like a belt (**blue areas**). The regions identified so far are located in the left temporal pole (**TP**), left inferotemporal cortex (**It**), and left prefrontal cortex (**Pf**). The left basal ganglia complex (not pictured) is an integral part of the language implementation system. (Courtesy of H. Damasio.)

The specific origins of language are obscure. *Homo habilis*, which lived about 2.5 to 2 million years ago, left behind caches of stone tools that may have served as home bases or butchering stations. The sharing of skills required to make the tools, and the social coordination required to share the caches, may have made it necessary for *H. habilis* to put simple language to use, though this is speculation. The skulls of *H. habilis* bear faint imprints of the gyral patterns of their brains, and some of the areas involved in language in modern humans (Broca's area and the supramarginal and angular gyri) are visible and are larger in the left hemisphere. We cannot be sure, of course, that these areas were used for language, since they have homologs even in monkeys, but the homologs play no role in the monkeys' vocal communication. *Homo erectus*, which spread from Africa across much of the Old World from 1.5 million to 500,000 years ago, controlled fire and used a stereotyped kind of stone hand ax. It is easy to imagine some form of language contributing to such successes, though again we cannot be sure.

The first *Homo sapiens*, thought to have appeared about 200,000 years ago and to have moved out of Africa 100,000 years ago, had skulls similar to ours and much more elegant and complex tools showing considerable regional variation. They almost certainly had language, given that their anatomy suggests they were biologically very similar to modern humans and that all modern humans have language. The major human races probably diverged about 50,000 years ago, which puts a late boundary on the emergence of language, because all modern races have indistinguishable language abilities.

The Study of Aphasia Led to the Discovery of Critical Brain Areas Related to Language

The lack of a homolog to language in other species precludes the attempt to model language in animals, and our understanding of the neural basis of language must be pieced together from other sources. By far the most important source has been the study of language disorders, known as *aphasias*, which are caused by focal brain lesions that result, most frequently, from stroke or head injury.

The early study of the aphasias paved the way for a number of important discoveries on the neural basis of language processing. First, it suggested that in a majority

P.1175

of individuals language depends principally on left hemisphere rather than on right hemisphere structures. All but a few right-handed individuals have left cerebral dominance for language, and so do most left-handed individuals. All told, about 96% of people depend on the left hemisphere for language processing related to grammar, the lexicon, phonemic assembly, and phonetic production. Even languages such as American Sign Language, which rely on visuomotor signs rather than auditory speech signs, depend primarily on the left hemisphere. Second, the early study of aphasia revealed that damage to each of two cortical areas, one in the lateral frontal region, the other in the posterior superior temporal lobe, was associated with a major and linguistically different profile of language impairment. The two cortical areas are Broca's area and Wernicke's area (Figure 59-1).

These findings allowed neurologists to develop a model of language that has become known as the Wernicke-Geschwind model. The earliest version of this model had the following components. First, two areas of the brain, Wernicke's and Broca's, were assumed to have the burden of processing the acoustic images of words and the articulation of speech, respectively. Second, the arcuate fasciculus was thought to be a unidirectional pathway that brought information from Wernicke's area to Broca's area. Third, both Wernicke's and Broca's areas were presumed to interact with the polymodal association areas. After a spoken word was processed in the auditory pathways and the auditory signals reached Wernicke's area, the word's meaning was evoked when brain structures beyond Wernicke's area were activated.

Similarly, nonverbal meanings were converted into acoustic images in Wernicke's area and turned into vocalizations after such images were transferred by the arcuate fasciculus into Broca's area. Finally, reading and writing ability both depended on Wernicke's and Broca's areas, which, in the case of reading, received visual input from left visual cortices and, in the case of writing, could produce motor output from Exner's area (in the premotor region above Broca's area).

This general model formed the basis for a useful classification of the aphasias (Table 59-1) and provided a framework for the investigation of the neural basis of language processes. However, several decades of new lesion studies and research in psycholinguistics and experimental neuropsychology have shown that the general model has important limitations. In particular, much progress has come from the advent of new methodologies, including positron emission tomography (PET), functional magnetic resonance imaging (fMRI), event-related electrical potentials (ERP), and the direct recording of electrical potentials from the exposed cerebral cortex of patients undergoing surgery for the management of intractable epilepsy. Each of these techniques has contributed to a better definition of the areas important for the performance of language tasks.

As a result of these advances, it now is apparent that the roles of Wernicke's and Broca's areas are not as clear as they first appeared. Similarly, the arcuate fasciculus is now appreciated to be a bidirectional system that joins a broad expanse of sensory cortices with prefrontal and premotor cortices. Finally, a variety of other regions in the left hemisphere, both cortical and subcortical, have been found to be critically involved in language processing. These include higher-order association cortices in the left frontal, temporal, and parietal regions, which seem to be involved in mediating between concepts and language; selected cortex in the left insular region thought to be related to speech articulation; and prefrontal and cingulate areas that implement executive control and mediation of necessary memory and attentional processes. The processing of language requires a large network of interacting brain areas.

The modern framework that has emerged from this work suggests that three large systems interact closely in language perception and production. One system is formed by the language areas of Broca and Wernicke, selected areas of insular cortex, and the basal ganglia. Together, these structures constitute a *language implementation system*. The implementation system analyzes incoming auditory signals so as to activate conceptual knowledge and also ensures phonemic and grammatical construction as well as articulatory control. This implementation system is surrounded by a second system, the *mediational system*, made up of numerous separate regions in the temporal, parietal, and frontal association cortices (Figure 59-1). The mediational regions act as third-party brokers between the implementation system and a third system, the *conceptual system*, a collection of regions distributed throughout the remainder of higher-order association cortices, which support conceptual knowledge.

Broca Aphasia Results From a Large Frontal Lobe Lesion

Broca aphasia is not a single entity. True persisting Broca aphasia is a syndrome resulting from damage to Broca's area (the inferior left frontal gyrus, which contains Brodmann's areas 44 and 45); surrounding frontal fields (the external aspect of Brodmann's area 6, and areas 8, 9, 10, and 46); the underlying white matter, insula, and basal ganglia (Figure 59-2); and a small portion of the anterior superior temporal gyrus. The patient's speech is labored and slow, articulation is impaired, and the melodic intonation of normal speech is lacking (Table 59-2). Yet patients have considerable success at verbal

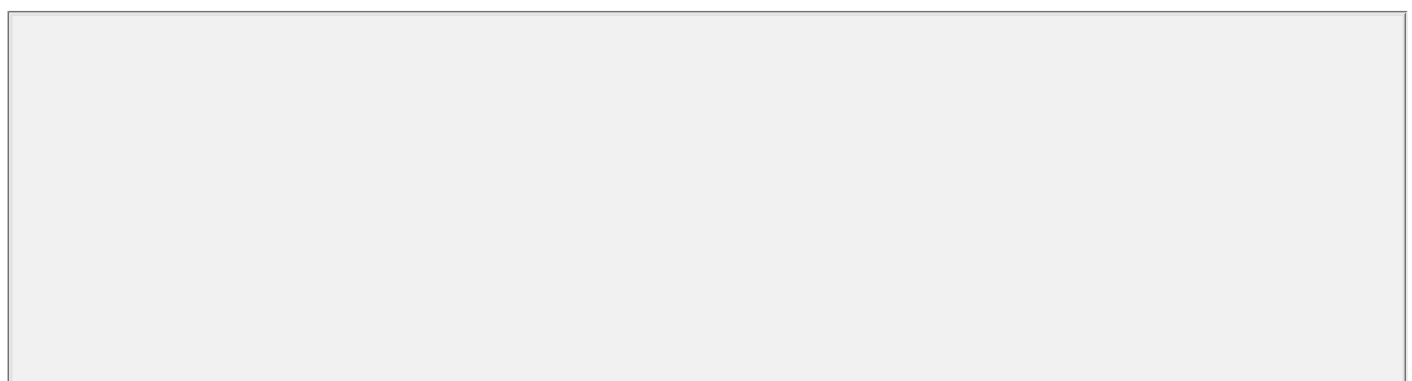

P.1176

P.1177

communication even when their words are difficult to understand because the selection of words, especially nouns, is often correct. Verbs, as well as grammatical words such as conjunctions, are less well selected and may be missing altogether. Another major sign of Broca aphasia is a defect in the ability to repeat complex sentences spoken by the examiner. In general, patients with Broca aphasia appear to comprehend the words and sentences they hear, but the comprehension is only partial, as we shall see below.

Table 59-1 Differential Diagnosis of the Main Types of Aphasia

Type of aphasia	Speech	Comprehension	Capacity for Repetition	Other Signs	Region Affected
Broca's	Nonfluent, effortful	Largely preserved for single words and grammatically simple sentences	Impaired	Right hemiparesis (arm > leg); patient aware of defect and may be depressed	Left posterior frontal cortex, and underlying structures
Wernicke's	Fluent, abundant, well articulated, melodic	Impaired	Impaired	No motor signs; patient may be anxious, agitated, euphoric, or paranoid	Left posterior, superior, and middle temporal cortex
Conduction	Fluent with some articulatory defects	Intact or largely preserved	Impaired	Often none; patient may have corticofugal sensory loss or weakness in right arm	Left superior temporal and supramarginal gyri
Global	Scant, nonfluent	Impaired	Impaired	Right hemiplegia	Massive left perisylvian lesion
Transcortical Motor	Nonfluent, explosive	Intact or largely preserved	Intact or largely preserved	Sometimes right-sided weakness	Anterior or superior to Broca's area
Transcortical Sensory	Fluent; scant	Impaired	Intact or largely preserved	No motor signs	Posterior or inferior to Wernicke's area,

Figure 59-2 Broca aphasia. Left: A three-dimensional magnetic resonance imaging (MRI) reconstruction of a lesion (an infarction in the left frontal operculum, dark gray area) in a patient with Broca aphasia. Right: Coronal section of the same brain taken along the plane defined by the blue slab. The brain is viewed from the front, with the left hemisphere on the right half of the image. The infarct is visible in black.

When damage is restricted to Broca's area alone, or to its subjacent white matter, a condition now known as *Broca area aphasia*, the patient develops a milder and transient aphasia rather than true Broca aphasia.

People With Broca Aphasia Have Trouble Understanding Grammatically Complex Sentences

Broca aphasia was initially thought to be a deficit of production only, because most patients give the impression of understanding casual speech. Modern psycholinguistic studies have shown that people who have Broca aphasia comprehend sentences whose meaning can be pieced together from the individual meanings of content words and prior knowledge of how the world works. For example, these patients can understand *The apple that the boy is eating is red*. Boys eat apples, but apples do not eat boys; apples are red, but boys are not. But they cannot comprehend sentences in which meaning depends on complex grammar. They cannot understand *The boy that the girl is chasing is tall*.

Aphasic patients can understand the first sentence, as well as much casual conversation in general, based on vocabulary and general knowledge, without exercising grammatical abilities. But they have difficulty with the second sentence because either boys or girls can be tall and either one can chase the other. The only way to understand the second sentence is to recover its phrase structure, look up the lexical entry of *chase* to find the positions of the chaser and the person being chased, and link the gap after *chasing* to *the boy*. People with Broca aphasia are tripped up by this demand, showing that their aphasia is not just a disorder of speech output but embraces deficits in syntactic processing.

Is Broca aphasia, then, a deficit of grammar, implying that Broca's area is the center for grammar? Not really. First, the speech of patients with Broca aphasia is not altogether devoid of grammatical structure. Their speech retains the phrase order of their particular language (eg, subject-verb-object in English, subject-object-verb in Turkish). Moreover, although grammatical suffixes such as *-ed*, *-ing*, and *-s* are often omitted in the speech of English-speaking aphasic patients, suffixes may be preserved in the speech of aphasic patients speaking other languages in which suffixes are obligatory to conform with the phonological structure of words. Second, people with Broca aphasia often can make surprisingly fine grammatical judgments, discriminating the grammatical and ungrammatical versions of sentences such as the following:

John was finally kissed by Louise.

John was finally kissed Louise.

I want you to go to the store now.

I want you will go to the store now.

For a sentence to be grammatically well formed, it needs certain functional *morphemes*—the smallest meaningful unit of a word. The ability of patients to recognize that a sentence needs these morphemes—combined with an inability to analyze those morphemes when understanding complex sentences—has been called the *"syntax-there-but-not-there" paradox*.

A possible resolution is that the major syntactic difficulty in Broca aphasia is linking up elements in different parts of the sentence that must refer to the same entity (anaphora and gap-filling). In *John was finally kissed by*

P.1178

P.1179

Louise, the failure to link *John* to the empty object position after *was kissed* would make the sentence incomprehensible. The aphasic person is able to detect the ungrammaticality of *John was finally kissed Louise* by simply noting that a passive verb (*was kissed*) appears illicitly with a direct object. This recognition does not depend on linking a gap with its filler. Indeed, people who have Broca aphasia *cannot* recognize that a sentence is ungrammatical if the ungrammaticality comes from an incorrect linkage between two separated elements in a sentence. That is, they are poor at discriminating between sentences such as the following pairs:

Table 59-2 Examples of Spontaneous Speech Production, Auditory Comprehension, and Repetition for the Primary Types of Aphasia			
Type of aphasia	Spontaneous speech	Auditory comprehension	Repetition
Broca	Stimulus (Western Aphasia Battery picnic picture): What do you see in this picture? "O, yea. Det's a boy an' a girl... an'... a... car... house... light po' (pole). Dog an' a... boat. 'N det's a... mm... a... cofee, an' reading. Det's a... mm... a... det's a boy... fishin'." (Elapsed time: 1 min 30 s)	Stimulus: What seems to be the trouble? "Yea, but, ah, notes an', ah... an', ah... I don' know."	Stimulus: The pastry cook was elated. "Elated."

Wernicke	"Ah, yes, it's, ah... several things. It's a girl... uncurl... on a boat. A dog...'S is another dog... uh-oh... long's... on a boat. The lady, it's a young lady. An' a man a They were eatin'. 'S be place there. This... a tree! A boat. No, this is a... It's a house. Over in here... a cake. An' it's, it's a lot of water. Ah, all right. I think I mentioned about that boat. I noticed a boat being there. I did mention that before.... Several things down, different things down... a bat... a cake... you have a..." (Elapsed time: 1 min 20 s)	"Well, I jus' lost a lot a time"	"/I/... no... In a fog."
Conduction	"Kay. I see a guy readin' a book. See a women / ka... he... /pouin' drink or somethin'. An' they're sittin' under a tree. An' there's a... car behind that an' then there's a house behind th' car. An' on the other side, the guy's flyin' a / fait... fait / (kite). See a dog there an' a guy down on the bank. See a flag blowin' in the wind. Bunch of/hi... a.../trees in behind. An a sailboat on th' river, river... lake. 'N guess that's about all... 'Basket there." The girl fixed herself a sandwich.

The girl fixed themselves a sandwich.

Linking two elements (filler to gap, or antecedent to pronoun) requires keeping the first element in one's working memory ([Chapters 19](#) and [62](#)) until the second is encountered and the two can be joined. This suggests that Broca's area and associated regions may participate in the verbal short-term memory required for sentence comprehension. Recent functional brain imaging studies using PET show that the level of activation in a subregion of Broca's area increases when a subject has to understand a sentence in which there is a long gap in the middle compared with the level when the subject must understand similar sentences with shorter gaps in the middle

The idea that Broca's area is related to short-term working memory fits with other findings. Working memory is thought to have a phonological loop consisting of a transient memory store for phonological information and a rehearsal process—a covert articulatory process in which commands are sent to the vocal tract muscles but not carried out—which repeatedly refreshes the memory. Broca's area may participate in the rehearsal component of the loop, something that accords with the well-documented role of Broca's area in articulation.

The structures usually damaged in true Broca aphasia and in Broca area aphasia may be part of a neural network involved in both the assembly of phonemes into words and the assembly of words into sentences. This network is thought to be concerned with relational aspects of language, which include the grammatical structure of sentences and the proper use of grammatical vocabulary and verbs. The other cortical components of the network are located in external areas of the left frontal cortex (Brodmann's areas 47, 46, and 9), the left parietal cortex (areas 40, and 39), and sensorimotor areas above the sylvian fissure between Broca's and Wernicke's areas (the lower sector of areas 3, 1, 2, and 4) and the insula.

Wernicke Aphasia Results From Damage to Left Temporal Lobe Structures

Wernicke aphasia is usually caused by damage to the posterior sector of the left auditory association cortex (Brodmann's area 22), although in severe and persisting cases there is involvement of the middle temporal gyrus and deep white matter ([Figure 59-3](#)). The speech of patients with Wernicke aphasia is effortless, melodic, and produced at a normal rate and is thus quite unlike that of patients with true Broca aphasia. The content, however, is often unintelligible because of frequent errors in the choice of words and *phonemes*, the individual sound units that make up morphemes ([Table 59-2](#)).

Patients with Wernicke aphasia often shift the order of individual sounds and sound clusters and add or subtract them to a word in a manner that distorts the intended phonemic plan. These errors are called *phonemic paraphasias* (*paraphasia* refers to any substitution of an erroneous phoneme or entire word for the intended, correct

P.1180

one). When phoneme shifts occur frequently and close together, words become unintelligible and constitute neologisms. Even when words are put together with the proper individual sounds, patients with Wernicke aphasia have great difficulty selecting words that accurately represent their intended meaning (known as a *verbal* or *semantic paraphasia*). For example, a patient may say *headman* for *president*.

These patients also have difficulty comprehending sentences uttered by others. Although this deficit is suggested by the Wernicke-Geschwind model,

Wernicke's area is no longer seen as the center of auditory comprehension. The modern view is that Wernicke's area is part of a processor of speech sounds that associates the sounds with concepts. This processing involves, in addition to Wernicke's area, the many parts of the brain that subserve grammar, attention, social knowledge, and knowledge of the concepts corresponding to the meanings of the words in the sentences.

Conduction Aphasia Results From Damage to Structures That Interact With Major Language Areas of the Brain

Patients with *conduction aphasia* comprehend simple sentences and produce intelligible speech but, like those with Broca and Wernicke aphasias, they cannot repeat sentences verbatim, cannot assemble phonemes effectively (and thus produce many phonemic paraphasias), and cannot easily name pictures and objects (the task called *confrontation naming*). Speech production and auditory comprehension are less compromised in conduction aphasia than in the two other major aphasias ([Table 59-2](#)).

Persistent conduction aphasia is caused by damage to the left superior temporal gyrus and the inferior parietal lobe (Brodmann's areas 39 and 40). The damage may extend to the left primary auditory cortex (Brodmann's areas 41 and 42), the insula, and the underlying white matter. There is no evidence that conduction aphasia is caused by a simple interruption or disconnection of the arcuate fasciculus alone, although the damage does destroy feed-forward and feedback projections that interconnect temporal, parietal, insular, and frontal cortices. This connectional system seems to be part of the network required to assemble phonemes into words and coordinate speech articulation.

Even though the exact anatomical correlates of conduction aphasia are being revised and the mechanism of the defect now appears not to be as proposed in the Wernicke-Geschwind model, Wernicke correctly predicted the main signs of the syndrome. This is a testimony to the considerable power of the early clinical observations in aphasia.

Transcortical Motor and Sensory Aphasias Result From Damage to Areas Near Broca's and Wernicke's Areas

The Wernicke-Geschwind model predicts that aphasias can be caused by damage not only to components of the language system but also to areas and pathways that connect those components to the rest of the brain. Patients with transcortical motor aphasia speak nonfluently but they can *repeat* even very long sentences. According to the Wernicke-Geschwind model, the aphasia is caused by a disconnection of the language areas from those that initiate and control spontaneous speech; repetition is preserved because the connection to Wernicke's area is intact.

The aphasia has been linked to damage to the left dorsolateral frontal area, a patch of association cortex anterior and superior to Broca's area, although there may be substantial damage to Broca's area itself. Dorsolateral frontal cortex is involved in the allocation of attention and the maintenance of higher executive abilities, including the selection of words. For example, part of the area is activated in PET studies when subjects have to produce the names of actions associated with particular objects (eg, saying *kick* in response to *ball*). Damage to this area leaves patients unable to perform such a task, although they can produce words in ordinary conversation.

The aphasia can also be caused by damage to the left supplementary motor area, located high in the frontal lobe, directly in front of the primary motor cortex and buried mesially between the hemispheres. Electrical stimulation of the area in nonaphasic surgery patients causes the patients to make involuntary vocalizations or be unable to speak, and neuroimaging studies have shown this area to be activated in tasks of speech production. Thus the supplementary motor area appears to contribute to the initiation of speech, whereas the dorsolateral frontal regions contribute to its ongoing control, particularly when the task is difficult.

People with transcortical sensory aphasia have fluent speech with impaired comprehension, and they also have great trouble naming things. This aphasia differs from Wernicke aphasia in the same way that transcortical motor aphasia differs from Broca aphasia: repetition is spared. In fact, patients with transcortical sensory aphasia may repeat and even make grammatical corrections in phrases and sentences they do not understand, and they can repeat words in foreign languages. The aphasia thus appears to be a deficit in semantic retrieval, with syntactic and phonological abilities still relatively intact.

Transcortical motor and sensory aphasias are believed to be caused by damage outside of the perisylvian area, in particular, outside the superior temporal and

P.1181

inferior parietal lobes, which explains the sparing of repetition skills. Transcortical aphasias are thus the complement of conduction aphasia, behaviorally and anatomically. Transcortical sensory aphasia itself appears to be caused by damage to parts of the junction of the temporal, parietal, and occipital lobes, which connect the perisylvian language areas with the parts of the brain underlying word meaning.

Figure 59-4 Positron emission tomography images compare the adjusted mean activity in the brain during separate tasks: naming of unique persons, animals, and tools. All sections are axial (horizontal) with left hemisphere structures on the right half of each image. The search volume (the section of the brain sampled in the analysis) includes inferotemporal and temporal pole regions (enclosed by the dotted lines). Red areas are statistically significant activity after correction for multiple comparisons. There are distinct patterns of activation in the left inferotemporal and temporal pole regions for each task. (Courtesy of H. Damasio.)

Global Aphasia Is a Combination of Broca, Wernicke, and Conduction Aphasias

Global aphasics have completely lost the ability to comprehend language, formulate speech, and repeat sentences, thus combining the features of Broca, Wernicke, and conduction aphasias. Speech is reduced to a few words at best. The same word may be used repeatedly, appropriately or not, in a vain attempt to communicate an idea. However, other abilities may be preserved: nondeliberate ("automatic") speech such as stock expletives (used appropriately and with normal phonemic, phonetic, and inflectional structures), routines such as counting or reciting the days of the week, and the ability to sing previously learned melodies and their lyrics. Auditory comprehension is limited to a few words and idiomatic expressions.

Classic global aphasia is accompanied by weakness in the right side of the face and paralysis of the right limbs and is caused by damage in the anterior language region and the basal ganglia and insula (as in Broca's area), the superior temporal gyrus (as in conduction aphasia), and the posterior language regions (as in Wernicke aphasia). So much damage can only be caused by a large infarct in the region supplied by the middle cerebral artery.

Beyond the Classic Language Areas: Other Brain Areas Are Important for Language

The anatomical correlates of the classical aphasias comprise only a restricted map of language-related areas in the brain. The past decade of research on aphasia has uncovered numerous other language-related centers in the cerebral cortex and in subcortical structures. Some are located in the left temporal region.

For example, until recently the anterior temporal and inferotemporal cortices, in either the left or the right

P.1182

hemisphere, had not been associated with language. Recent studies reveal that damage to left temporal cortices (Brodmann's areas 21, 20, and 38) causes severe and pure naming defects—impairments of word retrieval without any accompanying grammatical, phonemic, or phonetic difficulty. When the damage is confined to the left temporal pole (Brodmann's area 38) the patient has difficulty recalling the names of unique places and persons but not names for common things. When the lesions involve the left midtemporal sector (areas 21 and 20) the patient has difficulty recalling *both* unique and common names. Finally, damage to the left posterior inferotemporal sector causes a deficit in recalling words for particular types of items—tools and utensils—but not words for natural things or unique entities. Recall of words for actions or spatial relationships is not compromised.

These findings suggest that the left temporal cortices contain neural systems that access words denoting various categories of things but not words denoting the actions of the things or their relationships to other entities. Localization of a brain region that mediates word-finding for classes of things has been inferred from two types of studies: examination of patients with lesions in their brain from stroke, head injuries, herpes encephalitis, and degenerative processes such as Alzheimer disease and Pick disease, and functional imaging studies of normal individuals and electrical stimulation of these same temporal cortices during surgical interventions (Figure 59-4).

Another area not included in the classical model is a small section of the insula, the island of cortex buried deep inside the cerebral hemispheres (Figure 59-5). Recent evidence suggests that this area is important for planning or coordinating the articulatory movements necessary for speech. Patients who have lesions in this area have difficulty pronouncing phonemes in their proper order; they usually produce combinations of sounds that are very close to the target word. These patients have no difficulty in perceiving speech sounds or recognizing their own errors and do not have trouble in finding the word, only in producing it. This area is also damaged in patients with true Broca aphasia and accounts for much of their articulatory deficits.

The frontal cortices in the mesial surface of the left hemisphere, which includes the supplementary motor area and the anterior cingulate region (also known as Brodmann's area 24), play an important role in the initiation and maintenance of speech. They are also important to attention and emotion and thus can influence many higher functions. Damage to these areas does not cause an aphasia in the proper sense but impairs the initiation of movement (akinesia) and causes *mutism*, the complete absence of speech. Mutism is a rarity in aphasic patients and is seen only during the very early stages of the condition. Patients with akinesia and mutism fail to communicate by words, gestures, or facial expression. They have an impairment of the drive to communicate, rather than aphasia.

The Right Cerebral Hemisphere Is Important for Prosody and Pragmatics

In almost all right-handers, and in a smaller majority of left-handers, linguistic abilities—phonology, the lexicon, and grammar—are concentrated in the left hemisphere. This conclusion is supported by numerous studies of patients with brain lesions and studies of electrical and metabolic activity in the cerebral hemispheres of normal people. In "split-brain" patients, whose corpus callosum has been sectioned to control epilepsy, the right hemisphere occasionally has rudimentary abilities to comprehend or read words, but syntactic abilities are poor, and in many cases the right hemisphere has no lexical or grammatical abilities at all.

Nonetheless, the right cerebral hemisphere does play a role in language. In particular, it is important for communicative and emotional prosody (stress, timing, and intonation). Patients with right anterior lesions may produce inappropriate intonation in their speech; those with right posterior lesions have difficulty interpreting the emotional tone of others' speech. In addition, the right hemisphere plays a role in the *pragmatics* of language. Patients with damage in the right hemisphere have difficulty incorporating sentences into a coherent narrative or conversation and using appropriate language in particular social settings. They often do not understand jokes. These impairments make it difficult for patients with right hemisphere damage to function effectively in social situations, and these patients are sometimes shunned because of their odd behavior.

When adults with severe neurological disease have the entire left hemisphere removed, they suffer a permanent and catastrophic loss of language. In contrast, when the left hemisphere of an infant is removed the child learns to speak fluently. Adults do not have this plasticity of function, and this age difference is consistent with other findings that suggest there is a critical period for language development in childhood. Children can acquire several languages perfectly, whereas most adults who take up a new language are saddled with a foreign accent and permanent grammatical errors. When children are deprived of language input because their parents are deaf or depraved, they can catch up fully if exposed to language before puberty, but they are strikingly inept if the first exposure comes later.

Figure 59-5

A. Lesions of 25 patients with deficits in planning articulatory movements were computer-reconstructed and overlapped. All patients had lesions that included a small section of the insula, an area of cortex underneath the frontal, temporal, and parietal lobes. The area of infarction shared by all patients is depicted here in **dark purple**.

B. The lesions of 19 patients without a deficit in planning articulatory movements were also reconstructed and overlapped. Their lesions completely spare the precise area that was infarcted in the patients with the articulatory deficit. (For this figure, left hemisphere lesions were reconstructed on the left side of the image.)

P.1183

Despite the remarkable ability of the right hemisphere to take on responsibility for language in young children, it appears to be less suited for the task than the left hemisphere. One study of a small number of children in whom one hemisphere had been removed revealed that the children with only a right hemisphere were impaired in language (and other aspects of intellectual functioning), compared with children who had only a left hemisphere (these children were less impaired overall). Like people with Broca aphasia, children with only a right hemisphere comprehend most sentences in conversation but have trouble interpreting more complex constructions, such as sentences in the passive voice. A child with only a left hemisphere, in contrast, has no difficulty even with complex sentences.

Alexia and Agraphia Are Acquired Disorders of Reading and Writing

Certain brain lesions in adults can cause *alexia* (also known as word blindness), a disruption of the ability to read, or *agraphia*, a disruption of the ability to write. The two disorders may appear combined or separately, and they may or may not be associated with aphasia, depending on the site of the causative lesion. Reading emerged only recently in history (less than 5000 years ago), and universal literacy is even more recent (less than a century ago). Therefore, pure alexia without aphasia cannot be attributed to impairment of a special "reading system" in the brain but must be caused by a disconnection between the visual and language systems.

Because vision is bilateral and language is lateralized, pure alexia results from disruptions in the transfer of visual information to the language areas of the

left hemisphere. In 1892 the French neurologist Jules Dejerine studied an intelligent and highly articulate man who had recently lost the ability to read, even though he could spell, understand words spelled to him, copy written words, and recognize words after writing the individual letters. The patient could not see color in his right visual field, but his vision was otherwise intact in both visual fields. Postmortem examination revealed damage in a critical area of the left occipital region that

P.1184

disrupted the transfer of visually related signals from *both* the left and right visual cortices to language areas in the left hemisphere. The postmortem examination also revealed some damage to the *splenium*, the posterior portion of the corpus callosum that interconnects left and right visual association cortices. This lesion is no longer believed to be involved in pure alexia, however. When the splenium is cut for surgical reasons without damaging visual cortices, the patient can read words normally in the right visual field but not those in the left.

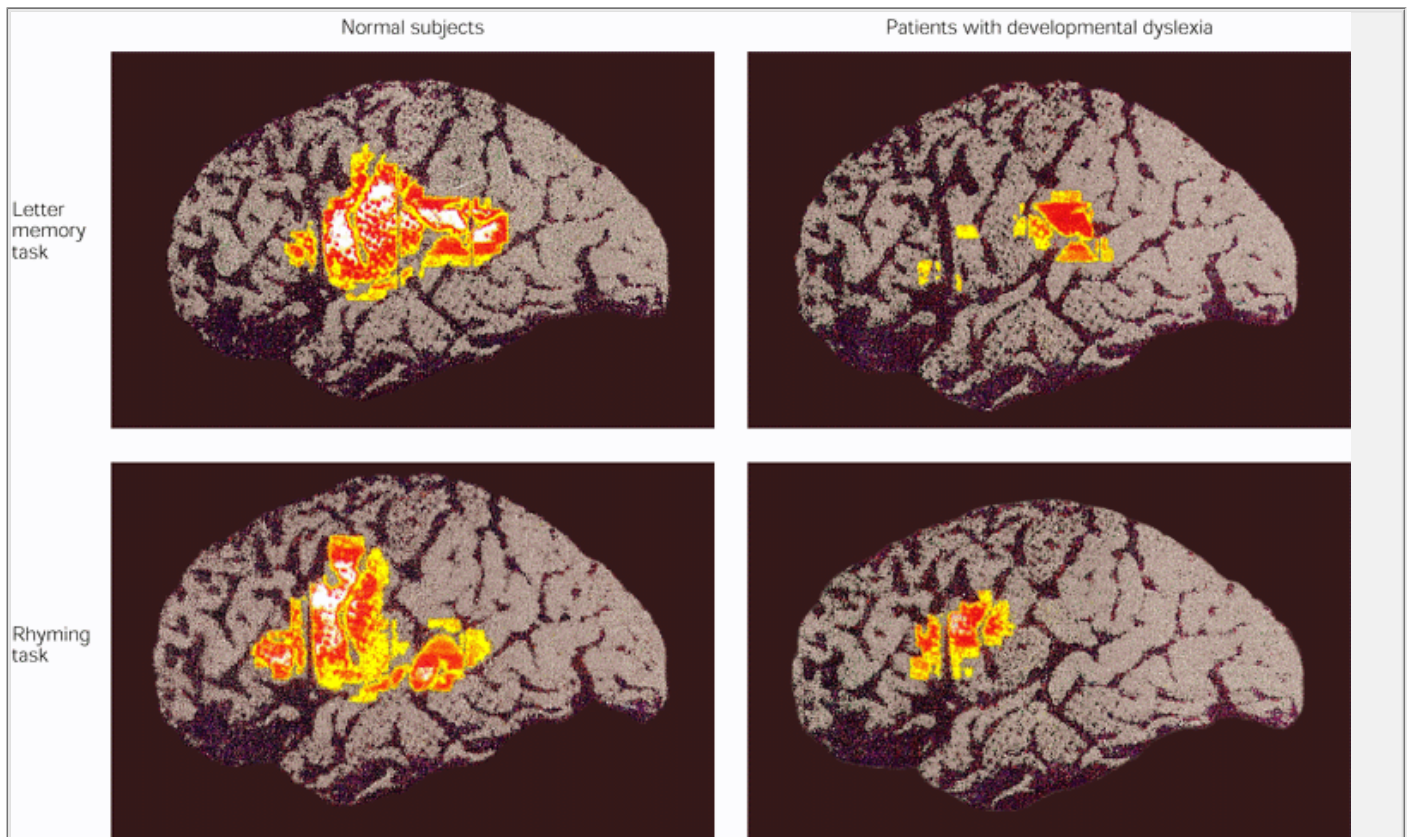

Figure 59-6 Areas of significant change in activity, indexed by perfusion, when subjects performed two language tests. The activated areas are superimposed on a lateral projection of the dominant left hemisphere with the frontal lobe to the left. The two pictures on the **left** are the results from normal subjects and the pictures on the **right** demonstrate results from patients with developmental dyslexia.

Memory task: The upper two images demonstrate activity associated with remembering short lists of letters. In the normal subject an extensive area involving the inferior left frontal cortex, the superior temporal cortex, and the inferior parietal cortex is activated. In dyslexic patients only the inferior parietal and superior temporal cortex are activated.

Rhyming task: During a rhyming task (lower images) that engages inner speech almost exclusively without taxing phonological memory, the inferior frontal and superior temporal cortex are activated in normal subjects, but only the inferior frontal cortex is activated in dyslexic subjects. Thus, dyslexic patients are able to activate each component of the verbal working memory system separately, but, unlike normal subjects, integrated activity between the precentral and postcentral structures appears defective. (Courtesy of R. Frackowiack.)

PET studies have shown that reading words and word-like shapes selectively activates extrastriate left cortical areas anterior to the visual cortex. This suggests that the processing of word shapes, like other complex visual qualities, requires that general region.

Developmental Dyslexia Is a Difficulty in Learning to Read

A more prevalent form of reading disorder is seen in children who have difficulty in learning to read and spell despite normal eyesight and hearing, adequate education, and normal IQ. This syndrome, called *developmental dyslexia*, has been estimated to affect between 10 and 30% of the population. As mentioned earlier, reading is a complex and historically recent skill, and it is unlikely that

P.1185

there is a well-defined system in the brain dedicated to it. Many disorders of visual and language processing could disrupt reading, and dyslexia is probably a condition with several possible causes rather than a single syndrome.

Most children with dyslexia have not developed phonological awareness: the ability to attend to individual sounds, particularly phonemes, in the continuous speech wave and to associate them with letters. However, they understand other communicative symbols—such as traffic signs or words—that have a unique visual appearance, such as the Coca Cola trademark. Indeed, studies in the United States have shown that some dyslexic children can learn to read English when entire words are represented by single characters rather than a sequence of characters.

Defects in visual processing can also lead to developmental dyslexia. Similarities between dyslexia and alexia caused by stroke suggest that developmental dyslexia might sometimes result from abnormalities in connections between visual and language areas.

Some dyslexic children also exhibit a tendency to read words backward (eg, confusing *saw* and *was*) and have difficulty distinguishing letters that are mirror images of each other—such as *b* and *d*—both in reading and writing. These errors, together with the disproportionate number of left-handers among dyslexics, suggest that dyslexia might involve a deficit in the development of hemispheric specialization. In fact, in dyslexic males, unlike in normal males, the left planum temporale is not much larger than the right one, and it shows cytoarchitectonic abnormalities, including an incomplete segregation of cell layers and clusters of inappropriately connected neurons. Thus the migration of neurons to the left temporal cortex during development may have been

slowed in some dyslexic patients.

Another possible problem in dyslexia is an inability to process transient sensory input quickly. The normally rapid conduction in the magnocellular pathway of the visual system ([Chapter 27](#)) is below average in people with dyslexia, whereas conduction in the parvocellular pathway is normal. In particular, dyslexic patients have difficulty processing fast, high-contrast, visual stimuli. A plausible anatomical correlate of this disorder is seen in some dyslexic patients examined at autopsy: the cells in the magnocellular layers of the lateral geniculate nucleus are abnormally small compared to parvocellular layers and compared to magnocellular layers in control subjects. A similar defect is sometimes evident in the fast-conducting component of the auditory pathways ([Chapter 30](#)).

In addition to these processing impairments, patients who have developmental difficulties with reading can have other neuropsychological deficits ([Figure 59-6](#)). Such linkages must be considered tentative, however, until there is finer delineation of the disorders currently lumped together as dyslexia.

An Overall View

The study of language processing in the brain has come a long way in a century, but the challenges to understanding it are formidable. Great progress has been made since Broca's and Wernicke's seminal discoveries, and that progress has brought a more complete understanding of linguistic processes and an appreciation of the complex ways in which they interconnect with systems for perception, motor control, conceptual knowledge, and attention.

Several developments offer the hope of even greater progress in the near future. Improvements in anatomical imaging will allow more precise and consistent delineation of lesions that affect specific features of language ability, and greater involvement by linguists and experimental psychologists will allow more precise and consistent delineation of the deficits in functioning.

Measurement of brain activity in normal subjects, using PET, functional MRI, and magnetoencephalography (MEG), will become more important in the next few years as the spatial and temporal resolution of these techniques improves and the most sophisticated experimental paradigms and linguistic analyses are systematically applied. Neurosurgical candidates, whose brain functions must be mapped by stimulation during surgery or recording from implanted electrode grids that remain in the skull during everyday activities, will be an important source of fine-grained information, especially if the language tasks administered to them are carefully constructed to isolate functions.

Progress in the understanding of language is important for the advancement of fundamental neuroscience and indispensable for the treatment of patients with aphasia, which is by far the most frequent impairment of higher function caused by stroke and head injury. The astonishing feat of language is too complex to be understood with the tools of any single academic or medical specialty, but as several disciplines come together to study the underlying neural processes, we can expect significant breakthroughs.

Disorders of Thought and Volition: Schizophrenia

Eric R. Kandel

THE SUCCESS OF NEUROBIOLOGY in providing insights into perception and language has inspired biological investigation into thought and mood and their disorders. In this chapter and the next we examine the four most serious disorders of thinking and mood: schizophrenia, depression, mania, and the anxiety states. These disorders involve disturbances in thought, self-awareness, perception, affect, volition, and social interaction.

In addition to being scientifically challenging, mental illness is of great social importance. Fully 10% of people with schizophrenia commit suicide. Many more are homeless. Before the advent of psychopharmacologic agents, schizophrenia and the affective disorders accounted for more than half of all hospital admissions in the United States. Even now schizophrenia accounts for about 30% of *all* hospitalizations.

Mental Illnesses Can Be Diagnosed Using Classical Medical Criteria

In medicine the term *disease* refers to a cluster of symptoms and signs that results from a specific cause and leads through a defined course to a specific outcome. As with other diseases of the brain, the analysis of a mental disease requires good delineation of the symptoms and signs. Ideally, a diagnosis is based on two additional factors: (1) a clear and evident *causative agent* (whether the illness results from a genetic abnormality, a viral or bacterial infection, toxins, tumors, or stress) and (2) a plausible *pathogenesis* (a clear idea of the mechanism by which the causative agent produces the disease).

Unfortunately, unlike most other medical illnesses, the causes and pathogenesis of most mental illnesses have not, as yet, been determined with certainty. As a result, psychiatric disorders are to a large extent still grouped today as they were in other areas of medicine at the beginning of the twentieth century. In other areas of medicine diseases were once grouped according to organ systems: lung, heart, gastrointestinal system, etc.

P.1189

Likewise, in psychiatry diseases were grouped according to which of the four major mental systems was affected: cognition, affect, intelligence, or social behavior. Thus the diseases are categorized as follows: (1) disorders of cognition (schizophrenia and delirium); (2) disorders of mood (affective disorders and anxiety states); (3) disorders of learning, memory, and intelligence (mental retardation and dementia); and (4) disorders of social behavior (personality disorders).

This classification derives importantly from the work at the turn of the century by Emil Kraepelin, the director of the Psychiatry Clinic at the University of Heidelberg in Germany. Before Kraepelin's initiative psychiatrists did not think of mental illnesses as diseases with a specific onset, progression, and outcome. They classified symptoms along arbitrary lines that had no medical significance. Influenced by Rudolf Virchow, the German pioneer of cellular pathology, and Thomas Sydenham, the English clinician who focused attention on the course of disease, Kraepelin began to study the disorders of mental faculties as specific disease processes. Kraepelin argued that even in the absence of empirical knowledge about etiology and pathogenesis, diseases of the mind could be distinguished descriptively on the basis of two classical approaches that had been followed in other areas of medicine.

First, mental disorders can be classified on the basis of signs (what the examiner sees) and symptoms (what the patient reports). Of course, the presentation of a single sign or symptom is not in itself evidence for disease, since it may occur in healthy people. But when certain signs and symptoms occur together in several patients, they are said to form a *syndrome*, a condition that can be distinguished from normal behavior or from other clusters of signs and symptoms.

Second, a mental disorder can be characterized on the basis of its *natural history*, by tracing the emergence of signs and symptoms at specific times in the patient's life and the evolution of these symptoms over time. Thus, a syndrome may be present at a characteristic age or be associated with a specific event, or it may follow a characteristic clinical course. For example, at least 33% of patients with schizophrenia deteriorate progressively, whereas most patients with the major affective disorders show cycles of relapse and recovery.

Since Kraepelin's pioneering work both approaches have been used to delineate a mental disease. The delineation of a mental disease can, in principle, be refined further by one of three measures:

- **Response to specific treatment.** A disease may respond specifically to a class of drugs that are not effective against other diseases. For example, manic-depressive illness responds to lithium, but other mental illnesses do not.
- **Pathologic condition.** The clinical diagnosis of diseases of the heart, lung, kidney, and intestines, and even many neurological diseases, can be confirmed by examining the structural and functional changes in the diseased tissue, and this examination in turn provides information about the pathogenesis of disease. The absence of anatomically demonstrable pathologic conditions distinguishes diseases of the mind from those of other areas of medicine, including neurology. Huntington disease, for example, is associated with a lesion in the head of the caudate nucleus.
- **Causality.** To conclude that a syndrome is the manifestation of a specific disease, specific causative agents must be identified. A syndrome need not have a single cause and therefore need not be a unitary disease. For example, the syndrome of pneumonia can be caused by different bacteria or different viruses giving rise to different specific diseases. The discovery of a specific molecular abnormality can provide particularly powerful insight into the cause of a disease. For example, in Duchenne muscular dystrophy the membrane-associated protein dystrophin is always absent or abnormal because of abnormalities in the gene encoding the protein.

Unfortunately, the pathogenesis of most psychiatric disorders has yet to be demonstrated. The defects underlying most psychiatric disorders are thought to involve subtle genetic, molecular, and anatomical changes, and these changes have remained elusive.

Psychiatric diagnosis therefore must rely heavily on the individual patient's history and the patient's response to treatment. Yet these clinical features can be hard to determine and even harder to quantify. In the past these limitations made it difficult to achieve consensus in the evaluation of psychiatric symptoms and to investigate psychiatric illness systematically. Today, however, substantial progress has been made in diagnosing mental illness and, as we shall see later, there is reason to hope that a genuine neuropathology of mental illness may emerge soon.

Schizophrenia Is Likely to Be Several Related Disorders

Schizophrenia is perhaps the most devastating disorder of humankind. Fairly common, it strikes about 1% of the population worldwide, and it seems to affect men

P.1190

slightly more frequently and severely than it does women. In addition to the 1% with schizophrenia, another 2-3% of the general population have *schizotypal personality disorder*, which is often considered to be a milder form of the disease because patients do not manifest overtly psychotic behavior.

Box 60-1 The Functional Neuroanatomy of Hallucinations in Schizophrenia

Imaging studies are beginning to shed light on the functional anatomy of hallucinations in schizophrenia. Frank Middleton and Peter Strick found that the basal ganglia, which are known to receive input from widespread areas of the cerebral cortex, including the frontal, parietal, and temporal lobes, project to both the frontal and the inferotemporal cortex.

The inferotemporal cortex is critically involved in the recognition and discrimination of visual objects and is the area disturbed in prosopagnosia, a disorder concerned with the recognition of faces (Chapters 25 and 28). The output nuclei of the basal ganglia—the substantia nigra pars reticulata— project via the thalamus to the inferotemporal cortex. Thus, the inferotemporal cortex is not only a source of input to the basal ganglia but also a target of basal ganglia output (Figure 60-1).

This result implies that the basal ganglia can influence higher-order visual processing, and that the basal ganglia loop may lead to alterations in visual perception, including visual hallucinations characteristic of schizophrenia. In fact, visual hallucinations are a major side effect of L-DOPA and other dopaminergic agents used in the treatment of Parkinson disease. Approximately 30% of patients with Parkinson disease treated in this manner experience this peculiar side effect.

The hallucinations in these patients may be due to excessive stimulation of the dopamine receptors in the visual striatum, which leads to a net increase in activity in the nucleus pars reticulata and thus abnormal increases in thalamic input to the inferotemporal cortex. Brain images of schizophrenic patients experiencing hallucinations support this hypothesis; the subjects display significant changes in blood flow at several brain sites that are part of the inferotemporal system (Figure 60-2).

Figure 60-1 Proposed loop between the basal ganglia and the inferotemporal cortex. In a series of PET studies five patients with classical auditory-verbal hallucinations received medication yet still hallucinated. PET scans taken during hallucinations demonstrated activation of thalamic and striatal nuclei as well as of the hippocampus, the paralimbic region, the cingulate cortex, and the orbitofrontal cortex. One patient who had never received drugs had visual as well as auditory hallucinations. That patient showed activation in visual and auditory language association cortices near Wernicke's area, part of a distributed cortical network involved in the hallucinations. The interaction of these distributed neural systems may provide a neuroanatomical basis for the bizarre behavior of patients with schizophrenia. The prominent feature in this group of patients is involvement of the thalamus and the lack of activation of Broca's area. **Shading** indicates the portion of each structure that contributes to the circuit. (Based on Silbersweig et al. 1995.)

Figure 60-2

A. Increased activity in the brain during auditory-verbal hallucinations. Functional PET results (**yellow and orange**) are superimposed on a magnetic resonance image for anatomical reference. Section numbers refer to the distance from the anterior commissure-posterior commissure line, with positive numbers being superior to the line. Activation (**yellow**) extends into the amygdala bilaterally and the right orbitofrontal cortex. These regions are consistent with activation of limbic, paralimbic, and inferotemporal system during hallucinations.

B.1. Two surface projections (left lateral and ventral) show brain areas with significantly increased activity during visual and auditory-verbal hallucinations.

2. Functional PET results (**yellow and orange**) are superimposed on the structural T_1 weighted MRI scan, illustrating several areas of activation.

In 1990 the annual cost of caring for patients with schizophrenia in the United States was estimated to be \$33 billion. This cost accounts for about 2.5% of the total annual expenditures for health care in the United States. Even more disturbing is the estimate that about 30% of all the homeless people in the United States have schizophrenia,

P.1191

and the homeless are not likely to be beneficiaries of the health care system. Thus the substantial funds being spent on the treatment of schizophrenia reach only a fraction of those afflicted with the disease. The increase in the incidence of schizophrenia among the homeless in the United States dates to 1960, with the movement away from institutional treatment for schizophrenia. (Before 1960 patients with schizophrenia were almost routinely committed for long-term in-hospital care.) At the same time, adequate community outpatient facilities have not been developed to handle the social problems of patients with chronic schizophrenia.

P.1192

Because of the prevalence and social cost of schizophrenia, a major effort has been expended to develop better criteria for diagnosing the illness. More precise criteria have emerged only recently. In the early 1900s two major types of mental disorders had been well delineated: *senile dementia*, the loss of cognitive capacities in certain elderly people (a disease we now recognize as Alzheimer disease), and *personality disorders*, disorders of social behavior. Based on a review of the signs and symptoms as well as long-term progress of hundreds of patients with a variety of mental disorders, Kraepelin defined two new syndromes.

One new syndrome he called *dementia praecox* (early deterioration of the intellect) because of its early age of onset (typically in adolescence as compared to senile dementia). Kraepelin observed that this syndrome often follows a progressive course without remission, leading ultimately to a dramatic deterioration of intellect. Kraepelin called the second newly defined syndrome *manic - depressive psychosis*. This condition usually has different symptoms—disturbances of mood rather than intellect—but most important it also has a very different course. Characteristically, the onset is later and is marked by remissions and relapses without progressive deterioration

Eugen Bleuler objected to the term *dementia praecox* because he saw some patients who became sick in adulthood rather than adolescence and other patients who occasionally experienced remission. He concluded that the symptoms described by Kraepelin did not reflect a single disease, but a group of closely related illnesses characterized by a specific disorder of cognition rather than a general deterioration of intellect (*dementia*). He proposed that the disorder was a fragmentation of the mind, with the result that cognitive processes were split off from volition, behavior, and emotion. Therefore Bleuler called this group of illnesses *schizophrenia*, a splitting of the mind. (This condition is not to be confused with multiple or split personalities, an uncommon disease in which a person alternately assumes two or more identities.) People with schizophrenia may show evidence of this splitting of the mind by having inappropriate *affect* (emotion). They may laugh while recounting a tragic event or may show no emotion (a flat affect) while describing a joyous occasion.

Schizophrenia is characterized by *psychotic episodes*— discrete, often reversible, mental states in which some of the patient's thought processes are not able to test reality correctly. During a psychotic episode patients are unable to examine their beliefs and perceptions realistically and to compare them to what is actually happening in the world. This *loss of reality testing* is accompanied by other disturbances of higher mental functioning, especially delusions (aberrant beliefs that fit in the face of facts and are not changed by evidence that the beliefs are unreasonable), hallucinations ([Box 60-1](#)), incoherent thinking, disordered memory, and sometimes confusion. For example, people with schizophrenia often hear internal voices (auditory hallucinations) that tell them things that are not true, for example that their parents are trying to poison them.

Psychotic episodes are not unique to schizophrenia and often also occur in affective disorders, brief reactive states, and states of toxic delirium (for example, psychosis resulting from the use of phencyclidine, also known as PCP or angel dust, which we shall learn about later). Using modern descriptive approaches, as given in the revised fourth edition of the *Diagnostic and Statistical Manual of the American Psychiatric Association* (DSM-IV), psychiatrists are now able to differentiate schizophrenia more clearly from other psychotic disorders with similar features that were formerly lumped with schizophrenia into a common diagnostic category. Modern diagnostic criteria include not only those features required to *make* the diagnosis (*inclusive criteria*) but also those that would cause one to *reject* it (*exclusive criteria*). Moreover, in actual clinical contexts independent observers agree on the usefulness of DSM-IV criteria in achieving accurate diagnoses.

Psychotic Episodes Are Preceded by Prodromal Signs and Followed by Residual Symptoms

The first psychotic episode of schizophrenia is often preceded by *prodromal signs*. These include social isolation and withdrawal, impairment in the normal fulfillment of expected roles, odd behavior and ideas, neglect of personal hygiene, and blunted affect. The prodromal period is then followed by one or more psychotic episodes that may include loss of reality testing, memory disturbances, delusions, and hallucinations. These episodes are sometimes separated by long periods in which the patient is not overtly psychotic but nonetheless behaves eccentrically, is socially isolated, and has a low level of emotional arousal (a flat affect), an impoverished social drive, poverty of speech, a poor attention span, and lack of motivation.

These symptoms of the nonpsychotic period are called *negative symptoms* because they reflect the absence of certain normal social and interpersonal behaviors. In contrast, the striking abnormalities of psychotic episodes are called *positive symptoms* because they reflect the presence of distinctively abnormal behaviors. The negative symptoms are chronic features of the illness and are the most difficult to manage.

Modern criteria for the diagnosis of schizophrenia require that a patient be continuously ill for at least six

P.1193

months and that there be at least one psychotic phase followed by a residual phase. During the psychotic episode one or more of the following three groups of positive symptoms must be present:

- Delusions (for example, the belief that one is being persecuted or that one's feelings, thoughts, and actions are controlled by an outside force).
- Prominent hallucinations, usually auditory (for example, hearing voices commenting on one's actions).
- Disordered thoughts, incoherence, loss of the normal association between ideas, or marked poverty of speech accompanied by a loss of emotional expression (flattening of affect).

During psychotic episodes patients with schizophrenia may also exhibit unusual postures, mannerisms, or rigidity. On the basis of these criteria and other differences, schizophrenia is often divided into subtypes, of which three are most readily distinguished: *paranoid schizophrenia*, a form more often found in men, in which systematic delusions of persecution predominate; *disorganized schizophrenia* (hebephrenia), a form characterized by early age of onset, a wide range of symptoms, and a profound deterioration of personality; and *catatonic schizophrenia*, a rare form in which mutism and abnormal postures dominate.

In diagnosing schizophrenia it is important to exclude a disorder of mood, especially manic-depressive illness or a drug-induced psychosis resulting from the use of amphetamine, PCP, or other psychostimulants. The prognosis for schizophrenia is generally (but not always) poor. There are frequent relapses into psychotic behavior, and each relapse in turn results in greater deterioration.

Some students of schizophrenia view the psychotic episodes (positive symptoms) and nonpsychotic episodes (negative symptoms) as different phases of the same disease, with the negative symptoms representing the long-term outcome of positive symptoms. However, other students of schizophrenia view the two types of symptoms as independent, arguing that negative and positive symptoms reflect two distinctive courses and underlying psychopathologies. According to this second view, patients in whom the negative symptoms predominate have a more severe illness, one in which the prognosis is poorer and in which, as we shall see later, there is more of a disturbance in the anatomy of the brain, especially more prominently enlarged ventricles, and more loss of cortical tissue. Negative symptoms are often associated with a history of poor social development before the onset of the disease, and this history of social withdrawal is perhaps the strongest predictor of a poor prognosis.

Genetic Predisposition Is an Important Factor

Identifying the causes of schizophrenia is one of the most challenging goals of psychiatric research. The only reliable clue as to cause comes from the finding that schizophrenia is due in part to a genetic abnormality.

The first direct evidence that genes are important in the development of schizophrenia was provided in the 1930s by Franz Kallmann. Kallmann was impressed when he discovered that the incidence of schizophrenia throughout the world is uniformly about 1%, even though social and environmental factors vary dramatically. He found, however, that the incidence of schizophrenia among parents, children, and siblings of patients with the disease is about 15%, strong evidence that the disease runs in families. A genetic basis for schizophrenia cannot simply be inferred from the increased incidence in families, however. Not all conditions that run in families are necessarily genetic—wealth and poverty and habits and values also run in families. In earlier times even the nutritional deficiency pellagra ran in families.

To distinguish genetic from environmental factors, Kallmann and other investigators developed several research strategies. One strategy was to compare the rates of illness in monozygotic (identical) and dizygotic (fraternal) twins. Monozygotic twins have essentially identical genomes; they share almost 100% of each other's genes. In contrast, dizygotic twins share only 50% of their genes and are genetically equivalent to siblings. If schizophrenia were caused entirely by genetic factors, monozygotic twins would have an identical tendency to have the disease develop. Even if genetic factors were necessary but not sufficient for the development of schizophrenia, because environmental factors were also involved, the monozygotic twin of a patient with schizophrenia would still be at

significantly higher risk than a dizygotic twin. The tendency for twins to have the same illness is called *concordance*. Studies of twins have established that the concordance for schizophrenia in monozygotic twins is about 45%, but in dizygotic twins only about 15%, about the same as for other siblings.

However, the high concordance in identical twins is still insufficient evidence for a genetic basis for schizophrenia, which can be explained as being acquired by learning from the disturbed behavior of the parents. To address this issue, and to disentangle further the effects of nature and nurture, Leonard Heston studied the rate of schizophrenia among adoptees in the United States, and Seymour Kety, David Rosenthal, and Paul Wender

P.1194

studied adoptees in Denmark. In both sets of studies the rate of schizophrenia was higher among the biological relatives of schizophrenic adoptees than among relatives of normal adoptees. The difference in rate, about 10-15%, was the same observed earlier by Kallmann (Table 60-1). In addition to documenting the importance of genetic factors in schizophrenia, these studies of adoptees in whom schizophrenia developed showed that rearing does not play a major role in the disease.

Table 60-1 Evidence for the Importance of Genetic Factors in Schizophrenia^a

	Biological relatives		Adoptive relatives	
	With schizophrenia	Control	With schizophrenia	Control
Chronic schizophrenia	2.9% ^b	0%	1.4%	1.1%
Latent schizophrenia	3.5	1.7	0	1.1
Schizophrenia, uncertain subtype	7.5 ^a	1.7	1.4	3.3
Total	14.0 ^a	3.4	2.7	5.5

^aAdapted from Kety et al. 1975.
^b Statistically significant.

Studies of adoptees further revealed that some of the blood relatives of adoptees with schizophrenia show odd behavior even if they do not manifest signs of schizophrenia—they are socially isolated, have poor rapport with people, ramble in their speech, tend to be suspicious, have eccentric beliefs, and engage in magical thinking. This group of symptoms, called *schizotypal personality disorder*, is thought to be a mild form of the disease, a nonpsychotic condition related to schizophrenia.

The familial pattern of schizophrenia is most dramatically illustrated in an analysis by Irving Gottesman, who ranked the relatives of Danish schizophrenics by the percentage of genes shared with the patient. He found a higher incidence of schizophrenia among first-order relatives (those who share 50% of the patient's genes, including siblings, parents, and children) than among second-order relatives (those who share 25% of the patient's genes, including aunts, uncles, nieces, nephews, and grandchildren). Even the third-degree relatives, who share only 12.5% of the patient's genes, had a higher incidence of schizophrenia than the 1% found in the population at large (Figure 60-3). These data strongly support a genetic contribution to schizophrenia.

If schizophrenia were caused entirely by genetic abnormalities, then the concordance rate for monozygotic twins, who share almost 100% of each other's genes, would be nearly 100%. The finding that the concordance rate in monozygotic twins is only about 45% indicates that the genetic transmission is unusual and that genetic factors are not the only cause.

Relatively routine studies of pedigrees often are sufficient to decide whether the mode of transmission of a disease is the classical dominant or recessive Mendelian inheritance of a single gene controlling the critical trait that is disordered. For example, Huntington disease is expressed in nearly 100% of those who carry the gene mutations associated with the disease at a single allele of the gene, and there are only minor nongenetic influences in the expression of this disease. Thus it could be said from pedigree inspection of Huntington disease, even before the mutant gene was discovered, that the disease is rare and fully penetrant and that all the symptoms are due to the transmission of a single dominant gene.

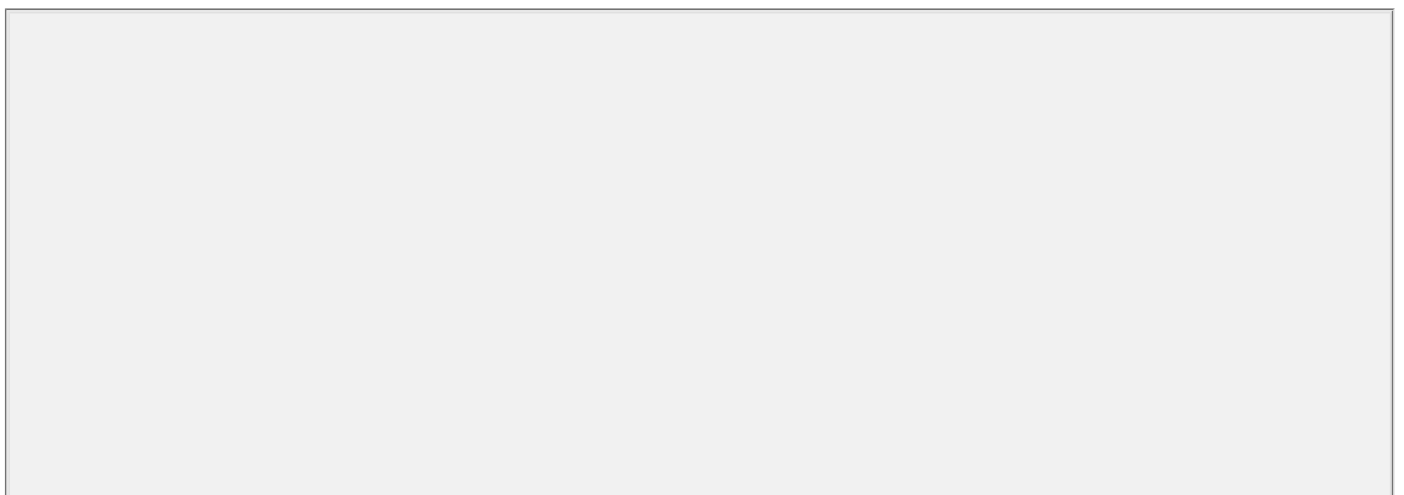

Schizophrenia clearly does not have this mode of transmission. Nor does it have the simple recessive mode of such diseases as phenylketonuria, in which both alleles of a single gene have to be defective for the clinical phenotype to be evident. In simple recessive disease neither parent may have the disease but one in four children will.

The most likely explanation for the unusual genetic transmission of schizophrenia—its high frequency of 1% and its partial penetrance—is that the illness is polygenic, involving in any given case perhaps as many as 3 to 10 genes. As with other polygenic diseases, such as diabetes and hypertension, it is possible that one or all of the critical genes are simply allelic variations—polymorphisms—of genes, each one of which by itself would not cause disease. Rather it is the *combination* of allelic polymorphisms in the context of a specific genetic background that is critical for the disease.

As this argument makes clear, in the case of polygenic diseases the distinction between mutations and allelic variations is not black and white. This is perhaps

P.1195

not surprising. With the exception of the genes that determine gender identity, people in the population at large do not differ from one another because they have different genes. We all have mainly the same genes. What distinguishes each of us from one another are a number of different alleles of the same genes.

Figure 60-3 The lifetime risk for schizophrenia is correlated with genetic relatedness to a person with schizophrenia. (From Gottesman 1991.)

The idea that schizophrenia is a polygenic disease is consistent with the evidence from other areas of behavioral genetics, which suggests that the normal range of variation for a given behavior or character type usually reflects the combined actions of many genes, each with only a small effect. Acting alone, most alleles alter behavior only subtly if at all. In fact, as we have learned, an allele that contributes to schizophrenia is not necessarily a mutation.

A search for particular allelic variations is now under way, applying genetic linkage analysis that makes use of both restriction fragment length polymorphisms and short tandem repeat polymorphisms that might contribute to schizophrenia. Recent studies of schizophrenia have uncovered two possible loci that correlate with schizophrenia. One locus is on the long arm of chromosome 22 (22q). The other is on chromosome 6 (6p). In each case the locus has been narrowed to a region containing about 50-100 genes.

Prominent Anatomical Abnormalities in the Brain Occur in Some Cases of Schizophrenia

Computerized tomography, magnetic resonance imaging, and cerebral blood flow studies have revealed that *some* patients with schizophrenia have one or more of four major anatomical abnormalities. First, early in the disease there is a reduction in the blood flow to the left globus pallidus (Figure 60-4), suggestive of a disturbance in the system that connects the basal ganglia to the frontal lobes. Second, there appears to be a disturbance in the frontal lobes themselves since blood flow does not increase during tests of frontal lobe function involving working memory, as it does in normal subjects. Third, the cortex of the medial temporal lobe is thinner and the anterior portion of the hippocampus is smaller than in normal people, especially on the left side, consistent with a defect in memory. Finally, the lateral and third ventricles are enlarged and there is widening of the sulci, especially in the thinner temporal lobe and in the frontal lobe, reflecting a reduction in the volume of this lobe as well.

The reduction in blood flow in the caudate nucleus and the frontal lobe, the reduced size of the hippocampus, the slightly enlarged ventricles, and the other structural changes of the brain are most commonly seen in patients who have prominent negative symptoms. These patients have a history of a prolonged prodromal period with poor social functioning before the onset of psychotic symptoms, suggesting that the disease starts early in life.

What is the relationship of these anatomical abnormalities to the genetic predisposition for schizophrenia? This question has been examined in a study of monozygotic twin pairs of which only one twin had schizophrenia. In 12 of 15 cases examined, the twin with

P.1196

schizophrenia had larger ventricles compared to the normal twin (Figure 60-5). The twin with schizophrenia almost invariably also had a smaller anterior hippocampus on the left side, and this reduction in hippocampal mass correlated highly with the reduction in blood flow in the left prefrontal cortex. Moreover, the smaller the hippocampal volume of the affected twin, the less the left prefrontal cortex was activated during a cognitive task. These several anatomical findings therefore suggest that the hippocampus, the prefrontal cortex, and the globus pallidus are part of a cognitive system that is impaired in schizophrenia.

Figure 60-4 Reduced blood flow in the left globus pallidus is one of the first anatomical abnormalities to appear in brain scans of patients with schizophrenia. This defect is thought to reflect a disturbance in an attentional system that involves both the basal ganglia and the frontal lobes.

Indeed, the negative symptoms of schizophrenia, which include a loss of executive functions such as planning and working memory, involve activities that normally require the prefrontal association areas ([Chapter 19](#)). In monkeys, for example, activation of these executive functions is correlated with increased metabolism in a distributed network that includes the anterior hippocampus, parietal cortex, and dorsolateral prefrontal cortex. A disturbance in this network could contribute to the negative symptoms of schizophrenia.

A Two-Step Model Seems Most Consistent With the Pathogenesis of Schizophrenia

The fact that twins who share identical genes have anatomical differences in their brains suggests that genes alone do not account for these structural changes. Rather, the structural changes presumably result from the combined actions of genes and some factors other than a genetic defect, perhaps a viral infection, a developmental abnormality, or a perinatal injury. Thus the development of schizophrenia may be a two-step process in which genetic predisposition is necessary but insufficient to produce the disease.

The possibility that developmental injury may be a causative agent in a two-step process that leads to schizophrenia is currently receiving much attention. Indeed, among the several anatomical defects that have been associated with schizophrenia, one developmental abnormality observed in a small group of patients by Edward Jones and his colleagues seems particularly interesting. This abnormality occurs in a population of neurons characterized histochemically by staining for the enzyme nicotinamide adenine dinucleotide phosphate diaphorase.¹ In normal people these neurons are found in white matter immediately below layer VI of the cortex. These neurons are part of the *cortical subplate*, a transitional structure that plays a key role in the formation of connections in the cerebral cortex ([Chapter 53](#)).

In patients with schizophrenia the number of these neurons in the superficial white matter of both the prefrontal and temporal lobe cortices is significantly reduced, whereas their number in the white matter deeper than 3 mm from the cortex is significantly greater compared to normal subjects. These differences suggest that, rather than remaining in the subplate region as they normally do, these neurons underwent abnormal migration during development. Since the subplate neurons are required for cortical development ([Chapter 55](#)), such a defect could lead to the establishment of abnormal patterns of cortical connections in the frontal and temporal lobes, the association areas thought to underlie the negative symptoms commonly observed in schizophrenia, and could contribute to their potential dysfunction.

What accounts for this disturbance in development? Some studies suggest that infants exposed to influenza during the second and third trimesters of gestation may have an increased risk for developing schizophrenia when they become adults, so that a viral infection during the mother's pregnancy might be responsible for the anatomical abnormalities. Alternatively, the migratory defect might reflect a premature switching off of genes involved in cell migration, genes that may respond to growth factors or their receptors. Thus, the genetic defects

P.1197

in schizophrenia may reflect an underlying failure to maintain the expression of one or another gene required to complete the process of cortical neuronal migration

Unaffected twin

Schizophrenic twin

Figure 60-5 Magnetic resonance images of monozygotic twins show marked enlargement of the lateral ventricle in the twin with schizophrenia. Enlargement of the ventricles has been found to correlate strongly with the presence of schizophrenia. (Adapted from [Suddath et al. 1990.](#))

It is likely, however, that these particular anatomical abnormalities in cortical development represent only one of a variety of basic anatomical defects that characterize the disease.

Antipsychotic Drugs Effective in the Treatment of Schizophrenia Act on Dopaminergic Systems

Until 1950 there was no effective treatment for schizophrenia. The first useful treatment was chlorpromazine, a drug that has a fascinating history. The French neurosurgeon Henri Laborit thought that anxiety experienced by patients before surgery led to the release of massive amounts of histamine from mast cells and that the histamines might contribute to the undesirable side effects of anesthesia, including sudden death. To block the release of histamine, Laborit examined various antihistaminics in an attempt to find one that would calm patients. Through trial and error he found chlorpromazine particularly effective.

Laborit was so impressed with the calming action of chlorpromazine that he began to think the drug might have a wider range of uses and soon appreciated that it might calm agitated patients with psychiatric conditions. In 1951 this idea was tested by John Delay and Pierre Deniker, who found that a high dosage of chlorpromazine calmed highly agitated and aggressive patients who had either schizophrenic or manic depressive symptoms.

Chlorpromazine was originally thought to act as a tranquilizer, calming patients without sedating them unduly. However, by 1964 it became clear that chlorpromazine and other related drugs of the phenothiazine class had specific effects on the psychotic symptoms of schizophrenia. The drugs mitigate or abolish delusions, hallucinations, and some types of disordered thinking ([Table 60-2](#)). Also, when patients who experience remission keep taking the antipsychotic medication throughout the period of remission, the rate of relapse is reduced.

These findings led to the delineation of a group of drugs, now called the *typical antipsychotics*, which include the phenothiazines (beginning with chlorpromazine), the

P.1198

butyrophenones (haloperidol), and the thioxanthenes ([Figure 60-6](#)). More recently a second group of drugs, the *atypical antipsychotics* (clozapine, risperidone, olanzapine), have also proved useful in the treatment of schizophrenia. Atypical antipsychotics are better than typical antipsychotics in treating negative symptoms (and cognitive defects) in schizophrenia, and they produce fewer side effects on the extrapyramidal systems.

A Phenothiazine derivatives:

Chlorpromazine (Thorazine)

Trifluopromazine

B Butyrophenones:

Haloperidol (Haldol)

C Thioxanthene derivatives:

Chlorprothixene

D Dibenzodiazepines:
Clozapine

Figure 60-6 The four major groups of antipsychotic drugs used to treat schizophrenia. The *typical antipsychotic* drugs—the phenothiazines (A), butyrophenones (B), and thioxanthenes (C)—bind to the dopaminergic D₂ receptors and have side effects in the extrapyramidal system, such as dry mouth and disorders of movement and gait. The *atypical antipsychotic* drugs, such as the dibenzodiazepine clozapine (D), bind primarily to dopaminergic D₃ and D₄ receptors and do not have extrapyramidal side effects.

How do the typical and atypical antipsychotic agents produce their actions? Paradoxically, the first clue to the cellular action of the typical antipsychotic drugs came from analysis of their side effects. The drugs often produce a syndrome resembling parkinsonism, a group of disorders that result from a deficiency in dopamine (Chapter 43). Following a suggestion by Arvid Carlsson, a number of studies soon found that many antipsychotic agents block dopamine receptors (Figure 60-7). This finding in turn suggested that perhaps excess dopamine transmission could be an important part of the pathogenesis of schizophrenia.

To determine whether dopaminergic transmission was excessive, it was important to identify the receptor sites at which the drugs exert their effect. At least six major types of dopamine receptors have now been cloned in humans: D₁, D₂, D₃, D₄, and D₅ (Figure 60-8). The amino acid sequences of each receptor subtype encode the seven membrane-spanning regions characteristic of G protein-coupled receptors (Table 60-3).

Figure 60-7 Chlorpromazine acts on dopamine receptors because it has a similar shape and therefore fits the receptor. However, because of differences in structure, chlorpromazine simply sits on the receptor, blocking it without triggering a response. (Adapted from Snyder 1986.)

P.1199

The D₁ and D₅ (also called D_{1b}) receptors are coupled to a G protein (G_s) that activates adenylyl cyclase, the enzyme that converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP) (Chapter 13). These receptors are expressed primarily in neurons of the cerebral cortex and hippocampus (although D₁ is also expressed in the caudate nucleus) and have a low affinity for most types of antipsychotic drugs.

The typical antipsychotic drugs have a high affinity for D₂ receptors, which are therefore thought to be one of the major sites of the therapeutic action of these drugs. Indeed, the clinical potency of the typical antipsychotic agents in patients with schizophrenia is closely correlated with the affinity of these drugs for the D₂ receptors (Figure 60-9).

Table 60-3 Five Major Types of Known Postsynaptic Dopamine Receptors

	D ₁	D ₂	D ₃	D ₄	D ₅
Molecular structure	Seven membrane-spanning regions	Seven membrane-spanning regions	Seven membrane-spanning regions	Seven membrane-spanning regions	Seven membrane-spanning regions
Effect on cyclicAMP	Increases	Decreases	Decreases	Decreases	Increases
Agonists	SKF 38393	Bromocriptine	7-OH-DPAT	?	SKF 38393
Antagonists	SCH 23390 Phenothiazines Thioxanthenes Butyrophenones	Sulpiride Phenothiazines Thioxanthenes Butyrophenones Clozapine	UH232		SCH 23390
			Clozapine	Clozapine	

AMP = adenosine monophosphate. SKF 38393 = Smith Kline French compound no. 38393. 7-OH-DPAT = 7-hydroxy-dipropylaminotetraol. SCH 23390 = Scherring A. G. compound no. 23390. UH232 = U. Hacksell compound no. 232.

The D₂ receptor is part of a family of related receptors (the D₂ group), which include D₃, and D₄. All three of these receptors are able to inhibit adenylyl cyclase (Figure 60-8). These receptors are expressed at particularly higher levels in neurons of the caudate nucleus, the

P.1200

putamen, and the nucleus accumbens, but D₂ receptors are also present in the amygdala, hippocampus, and parts of the cerebral cortex. Since the D₂ group is expressed in the caudate and putamen, these receptors presumably contribute to the side effects of the antipsychotic drugs on the extrapyramidal systems (Chapter 43). The amygdala, hippocampus, and neocortex, however, are possible sites of therapeutic action.

Figure 60-8 There are at least six types of dopamine receptors, four of which are illustrated here. The postsynaptic receptor D₂ inhibits adenylyl cyclase (AC) by an inhibitory G protein (G_i). The presynaptic inhibitory autoreceptor, thought to be D₃, regulates the amount of dopamine released in response to an action potential via a phosphoinositide second-messenger system (DAG = diacylglycerol; IP₃ = inositol triphosphate; PIP₂ = phosphoinositide diphosphate; PKC = protein kinase C). Both the presynaptic D₃ receptor and the postsynaptic receptor D₂ have a high affinity for the typical antipsychotic drugs (the phenothiazine, butyrophenone, and thioxanthene classes) and are thought to be key targets for the therapeutic actions of these drugs. The receptors D₁ and D₅ stimulate AC by a stimulatory G protein (G_s). These have a low affinity for the typical antipsychotic drugs and are therefore not thought to be involved in mediating the effects of these drugs on schizophrenic symptoms. The receptors D₃ and D₄ bind the atypical antipsychotic drugs.

The atypical antipsychotic agents, such as clozapine, bind to D₃ and even more effectively to D₄ receptors. These two subtypes of the D₂ group are expressed primarily in the limbic system (Chapter 50) and cortex; they are only weakly expressed in the basal ganglia. This selective distribution may explain why the atypical antipsychotic agents do not give rise to side effects in the extrapyramidal systems. Both the D₂ and D₃ receptors are of further interest because they are present on dopaminergic neurons themselves, on both the cell body and the terminals. Here they act as *inhibitory autoreceptors* (Chapter 14) to control both the rate of firing of the neuron and the release of dopamine by the action potential at the terminals (see Figure 60-8).

Abnormalities in Dopaminergic Synaptic Transmission Are Thought to Be Associated With Schizophrenic Symptoms

Excess Synaptic Transmission of Dopamine May Contribute to the Expression of Schizophrenia

The idea that excessive release of dopamine during synaptic transmission underlies at least some aspects of the pathogenesis of schizophrenia has received its primary

P.1201

support from pharmacologic studies. Drugs that increase the level of dopamine, such as L-dihydroxyphenylalanine (L-DOPA), cocaine, and amphetamine (Figure 60-10), can induce psychotic episodes resembling paranoid schizophrenia. Some of these drugs, such as amphetamine, also cause bizarre, repetitive, stereotyped behavioral acts in monkeys. Antipsychotic drugs reverse not only amphetamine psychosis in humans but also the bizarre behavioral syndrome in monkeys.

There is still no direct evidence, however, that excessive activity in dopaminergic neurons actually contributes to schizophrenia. The challenge in the study of schizophrenia, as with the depressive disorders that we shall consider in Chapter 61, is to advance from initial pharmacologic clues to precise physiological explanations of the pathogenesis of the disease. To explore further the role of dopaminergic transmission in schizophrenia we need to know which components of the dopamine system are altered in the disease and which of these alterations are related to specific neuroanatomic defects and clinical symptoms.

Distinct Anatomical Components of the Dopaminergic System Are Implicated in Schizophrenia

How are the dopaminergic neurons organized? Which particular grouping might contribute to schizophrenia? As we saw in Chapter 45, the dopaminergic neurons are not randomly distributed in the brain but are organized into four major systems: the tuberoinfundibular, nigrostriatal, mesolimbic, and mesocortical systems (Figure 60-11).

The dopaminergic *nigrostriatal system* contributes to the symptoms of Parkinson disease (Chapter 43). This system may also be involved in the short-term side

effects of antipsychotic medication on the pyramidal system, such as hand tremor and rigidity of muscles, as well as the long-term side effect called *tardive dyskinesia*, a disorder involving involuntary movements that prominently affects the tongue.

The dopaminergic *mesolimbic system* has its origin in cell bodies in the ventral tegmental area, which is medial and superior to the substantia nigra. These cells project to the mesial components of the limbic system: the nucleus accumbens, the ventral striatum, the nuclei of the stria terminalis, parts of the amygdala and hippocampus, the lateral septal nuclei, the entorhinal cortex, the mesial frontal cortex, and the anterior cingulate cortex. In view of the role of the mesolimbic system in emotions and memory (see [Chapters 50](#) and [62](#)), and the similarity in disturbances of thought and perception characteristic of schizophrenia and certain types of psychomotor (limbic system) epilepsy, Arvid Carlsson proposed that the positive symptoms of schizophrenia result from overactivity of the mesolimbic system. The idea that the mesolimbic dopaminergic system is affected in schizophrenia is supported by the finding that the earliest sign of brain disturbances in schizophrenia, detectable with positron emission tomography (PET) imaging, is a decrease in blood flow in a region of the basal ganglia ([Figure 60-4](#)). This disturbance is evident even before the prominent frontal lobe deficit becomes evident.

Among the projections of the mesolimbic system, those to the nucleus accumbens are thought to be particularly important because of the extensive connections of this nucleus to the limbic system. The nucleus accumbens receives and integrates inputs from the amygdala, hippocampus, entorhinal area, anterior cingulate area, and parts of the temporal lobe. The mesolimbic

P.1202

dopaminergic projection to the nucleus accumbens is thought to modulate these inputs and thereby influence the output of the nucleus accumbens to its target regions: the ventral pallidum, septum, hypothalamus, anterior cingulate area, and frontal lobes. As we have seen, some of the input sources, in particular the hippocampus, and some of the output targets, such as the cingulate cortex and the frontal lobes are thought to be disturbed in schizophrenia. Overactive modulation of the integration of the inputs to the nucleus accumbens and of the output from it could contribute to positive symptoms of schizophrenia ([Figure 60-12](#)).

Figure 60-9 The clinical potency of an antipsychotic drug and the ability of the drug to block dopamine D_2 receptors are strongly correlated. On the horizontal axis is the average daily dose required to achieve the same clinical effect. On the vertical axis is the concentration of drug required to bind half the receptors. The higher the concentration required, the lower the affinity for the receptor. (Adapted from [Seeman et al. 1976.](#))

Figure 60-10 The key steps in the synthesis and degradation of dopamine and the sites of action of various psychoactive substances at the dopaminergic synapse. (Adapted from Cooper et al. 1996.)

- 1. Enzymatic synthesis.** The dopamine precursor, dihydroxy-phenylalanine (**DOPA**), is synthesized from tyrosine by tyrosine hydroxylase. This action is stimulated by L-DOPA and blocked by the competitive inhibitor α -methyltyrosine.
- 2. Storage.** Reserpine and tetrabenazine interfere with the uptake and storage of dopamine by the storage granules. Reserpine is an effective antipsychotic drug; the depletion of dopamine by reserpine is long-lasting and the storage granules appear to be irreversibly damaged. Tetrabenazine also interferes with the uptake and storage mechanism of the granules, but only transiently.
- 3. Release.** Amphetamine and tyramide enhance dopamine release from dopaminergic neurons.
- 4. Receptor interaction.** Typical antipsychotics, such as perphenazine and haloperidol, are particularly effective in blocking the D_2 receptors and the presynaptic autoreceptors.
- 5. Reuptake.** Dopamine activity is terminated when dopamine is taken up into the presynaptic terminal. Cocaine, amphetamine, and the anticholinergic drug benzotropine are potent inhibitors of this reuptake mechanism. Amphetamine induces a psychosis that is reversed by antipsychotic drugs.
- 6. Degradation.** Dopamine in a free state within the presynaptic terminal can be degraded by the enzyme monoamine oxidase (**MAO**). Pargyline is an effective inhibitor of MAO. Dopamine can also be inactivated by the enzyme catechol-*O*-methyltransferase (**COMT**), which is believed to be localized in the postsynaptic cell.

The dopaminergic *mesocortical system* originates in the ventral tegmental area and projects to the neocortex, in particular the prefrontal cortex. The prefrontal cortex is involved in the temporal organization of behavior, in motivation, planning, attention, and social behavior (Chapter 20). The mesocortical system may be important in the negative symptoms of schizophrenia, symptoms that bear some resemblance to the defects seen after surgical disconnection of the frontal lobes, especially the dorsal prefrontal cortex. After loss of the dorsal prefrontal cortex, patients are poorly motivated, plan poorly, and have flattened affect.

The dopaminergic mesocortical system is essential for the normal cognitive functions of the dorsolateral prefrontal cortex. As is the case with ablating the prefrontal cortex, experimental depletion of dopamine in the prefrontal cortex (using the toxin 6-hydroxydopamine) impairs the performance of monkeys in cognitive tasks. This cognitive deficit can be reversed by giving the dopamine precursor L-DOPA or the agonist

P.1203

apomorphine. In fact, patients with Parkinson disease, who have lost dopaminergic neurons, not only have a motor disorder (reflecting the deficit in the dopaminergic nigrostriatal system) but also lack motivation and have flat affect and reduced spontaneity, defects that may reflect a decrease in transmission in the dopaminergic mesocortical pathways. Similarly, lesions that destroy the ventral tegmental area, which gives rise to the dopaminergic mesolimbic system, cause dementia and psychotic symptoms.

A Midsagittal section

B Coronal section

Figure 60-11 The four major dopaminergic tracts of the brain. The nigrostriatal system courses from the substantia nigra to the putamen and caudate. The tuberoinfundibular system originates in the arcuate nucleus of the hypothalamus and projects to the pituitary stalk. The mesolimbic system runs from the ventral tegmental area to many components of the limbic system. The mesocortical system projects from the ventral tegmental area to the neocortex, especially the prefrontal areas. We here only illustrate two of the four tracts. The mesolimbic system which may be involved in the positive symptoms of schizophrenia and the mesocortical system which may be involved in the negative symptoms.

These several findings led Daniel Weinberger to postulate that two dopaminergic systems are disturbed in different ways in schizophrenia. First, an increase in activity in the *mesolimbic* pathway (perhaps through the D₂ and D₃ receptors and particularly through the D₄ receptors) would account for the positive symptoms. Second, decreased activity of the *mesocortical* connections in the prefrontal cortex would account for the negative symptoms. According to this model, the imbalance between cortical and subcortical dopaminergic transmission underlies the development of schizophrenia. Weinberger proposes that activity in the mesocortical pathway to the prefrontal cortex normally inhibits the mesolimbic pathway by feedback inhibition and that the primary defect in schizophrenia is a reduction in this activity, which leads to disinhibition and overactivity in the mesolimbic pathway (Figure 60-13).

Although Weinberger's scheme is still untested, there is experimental evidence for interaction between the mesolimbic and mesocortical pathways. Christopher Pycock and his colleagues found that chemical lesioning of the mesocortical pathway in experimental animals enhances synaptic responsiveness in the mesolimbic pathway, specifically in its terminations in the nucleus accumbens. It is not known how loss of dopaminergic terminals in the prefrontal cortex leads to increased activity of the mesolimbic pathway in the nucleus accumbens. However, Pycock and his collaborators suggest that reduced activity in one pathway may result in compensatory neuronal growth in the other.

Figure 60-12 PET scans showing cerebral blood flow in schizophrenic patients during the performance of a cognitive task and after treatment with the dopamine agonist apomorphine. (From [Dolan et al. 1995](#).)

A. In patients with schizophrenia the anterior cingulate cortex fails to activate when they perform an internally generated task such as thinking of a word (as opposed to a task where the response is specified by an environmental cue, eg, saying a word displayed visually). When normal subjects are engaged in internally generated tasks, the anterior cingulate cortex is activated and the modality-specific temporal cortex around the auditory area is deactivated (PET scans not shown). In patients with schizophrenia this integrated activity in the frontotemporal system is impaired and indeed reversed: there is inadequate activation of the anterior cingulate cortex and excessive activation of the temporal lobes.

B. After these same schizophrenic patients received apomorphine, a dopamine agonist, activity in their anterior cingulate is greater than in normal subjects for the same task.

P.1204

Abnormalities in Dopaminergic Transmission Do Not Account for All Aspects of Schizophrenia

As these interesting but largely speculative arguments illustrate, we are far from understanding the role of dopaminergic transmission in normal mental function or in schizophrenia. The major argument for the involvement of dopaminergic pathways in schizophrenia comes from the analysis of the mechanisms of action of the antipsychotic drugs. It is difficult, in principle, to extrapolate from the mechanisms of action of a therapeutic agent to the causal mechanisms of a disease. Pharmacologic manipulation may produce changes that compensate for the disease without directly affecting the disordered mechanism itself. For example, the primary defect in Parkinson disease is a decrease in dopamine levels; but, as we have seen in [Chapter 43](#), some symptoms can be alleviated by drugs that block *cholinergic* transmission.

This issue can be further illustrated by the hypothetical situation of three presynaptic neurons converging on a postsynaptic neuron, with each presynaptic neuron releasing a different transmitter. Transmitter A and dopamine reduce the excitability of the postsynaptic cell, whereas transmitter B directly excites it ([Figure 60-14](#)). If schizophrenia resulted from a defect in neuron

P.1205

A or its transmitter, causing an excess of this modulatory transmitter to act on the postsynaptic cell, one could improve the symptoms by simply blocking the action of dopamine, the other modulatory transmitter, because this intervention would reduce net inhibitory inputs to the postsynaptic cell.

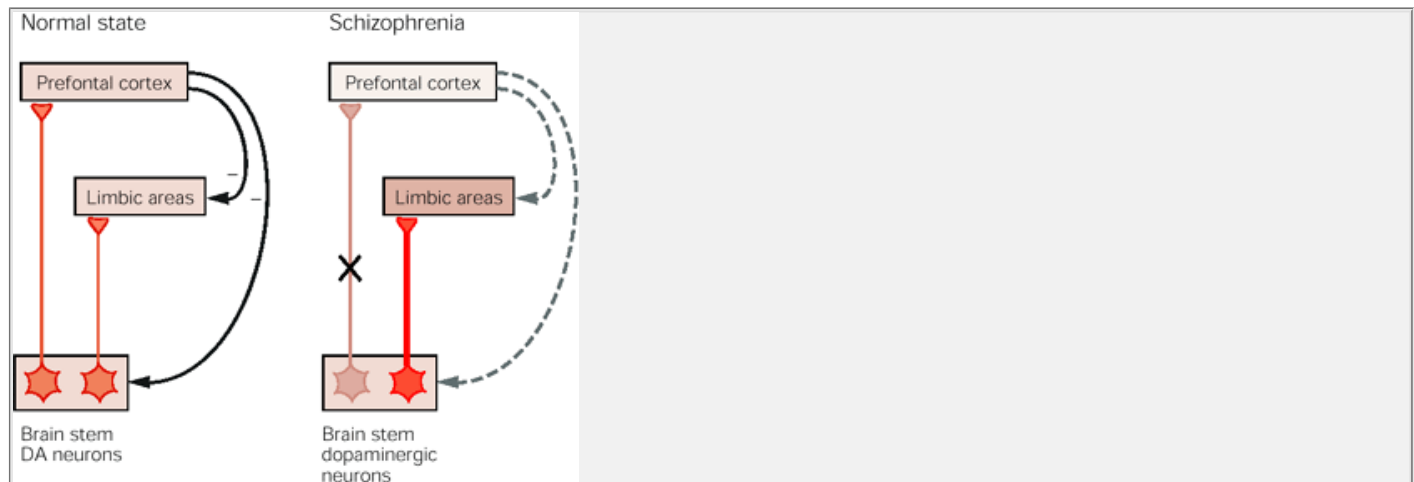

Figure 60-13 In this neuroanatomical model of schizophrenia the prefrontal cortex normally inhibits (through feedback inhibition) activity in the limbic areas and the dopaminergic mesolimbic pathway arising from the brain stem. A primary defect in schizophrenia may be depressed activity in the dopaminergic mesocortical projection from the brain stem to the frontal lobe, resulting in a loss of inhibitory feedback and consequent hyperactivity of the mesolimbic pathway. (Adapted from [Weinberger 1987](#).)

Figure 60-14 An antipsychotic drug that acts by blocking a dopamine receptor could ameliorate symptoms without directly acting on the neurons responsible for the disease. Here a cell receives inputs from excitatory cells (using transmitter substance B) and two types of inhibitory cells (using transmitter A or dopamine). If schizophrenia is due to an imbalance of synaptic input, specifically overactivity in the inhibitory neurons that use transmitter A, blocking the effectiveness of the dopaminergic inhibitory neurons could ameliorate the disease by reducing the net inhibition in the postsynaptic cell. However, it would be incorrect to assume that, because the block partially restored the balance and thereby improved the patient's behavior, the dopaminergic neurons were the site of pathology. (Adapted from R. Zigmond, personal communication.)

However, this model could easily prove inadequate for determining the best treatment. For instance, the dopaminergic neuron and neuron A might have very different inputs converging on them. If so, inhibiting dopaminergic transmission might cause an imbalance in the inputs and therefore inappropriate signals in the postsynaptic neuron. Even this simple example illustrates that a correlation between excess dopaminergic activity and schizophrenia, however strong, is not sufficient to allow a conclusion about the underlying cause of the disease.

In addition, there are some reasons to question whether the affinity of antipsychotic agents for D₂ (as well as D₃ and D₄) receptors is the only basis of the clinical efficacy of these drugs. Although antipsychotic drugs occupy dopamine receptors very quickly after administration,

P.1206

the maximal therapeutic (antipsychotic) effects are often delayed several weeks. Thus the acute blockade of dopaminergic transmission is not likely to be sufficient for the therapeutic effect. The antipsychotic action may be secondary to other consequences in the brain that evolve over a period of several weeks. For example, activity in certain neural circuits may need to adjust to a new level of modulation. In addition, the drugs or the resulting alterations in neuronal activity might produce changes in gene expression, the consequences of which may not become manifest for one or more weeks.

One late consequence of long-term dopamine blockade, which may well involve gene regulation, is an increase in the number of dopamine receptors per cell, and thus increased sensitivity to dopamine in each cell. A second late consequence, supported by electrophysiological data, is a decrease in the activity of dopaminergic neurons. Third, the delayed actions might also reflect adjustments of other neuronal systems that interact with the dopaminergic systems (see [Figure 60-10](#)). For example, most typical antipsychotic agents also act on a class of serotonin receptors, the 5-HT₂ receptors at which lysergic acid diethylamide (LSD) and other psychedelic hallucinogens also act (see [Chapter 61](#)). Long-term administration of antipsychotic agents leads to a downregulation of 5-HT₂ receptors that parallels in time course the therapeutic action of the antipsychotic drugs. Finally, many antipsychotic agents also bind the D₁ receptor, although with low affinity, and this may enhance the action of dopamine at the receptors of the D₂ group.

At least 20% of patients with schizophrenia do not improve after treatment with dopaminergic blockers that act on the group of D₂ receptors. But these patients often respond to atypical antipsychotic agents such as clozapine (a dibenzodiazepine), which is only a weak blocker of D₂ receptors. Clozapine has the additional interesting property that it produces few, if any, parkinsonian (extrapyramidal) side effects, which characteristically occur with blockade of D₂ receptors. Clozapine

and risperidone bind to D₃ receptors and even more effectively to D₄ receptors. As we have seen, D₃ and D₄ dopamine receptors are limited in their distribution to the limbic system.

Moreover, clozapine is not limited in its action to the dopamine system. It also blocks the serotonin receptor 5-HT_{2a} as well as the α₁ epinephrine and H₁ histamine receptors. Just as schizophrenia is a multifactorial disease and perhaps affects more than one set of dopaminergic pathways in the brain (mesolimbic and mesocortical), so it is likely that antipsychotic drugs act on more than one molecular target.

Further evidence that disorders in pathways other than the dopaminergic system might contribute to schizophrenia comes from the finding that the addictive drug phencyclidine (PCP) produces a psychosis that resembles the psychosis in schizophrenia and exacerbates psychosis in patients with schizophrenia. Normal subjects given intravenous PCP experience depersonalization and feel disconnected from their environment. They also have delusions of being controlled by external agents and have auditory and visual hallucinations.

PCP binds to two identified molecular targets in the brain: (1) the dopaminergic terminals in the nucleus accumbens, and (2) the N-methyl-D-aspartate (NMDA) class of glutamate receptors. NMDA receptors are present on the dopaminergic axon terminals in the prefrontal cortex and enhance dopamine release from the terminals. PCP, when it binds to the NMDA receptors, inhibits release of dopamine. In contrast, at the dopaminergic terminals in the nucleus accumbens PCP increases dopamine release and inhibits reuptake, much like amphetamine.

Thus, the behavioral effects of PCP may be due in part to its ability to enhance release in the mesolimbic pathway while blocking dopamine release in the mesocortical pathway. Indeed, specific drugs developed to block NMDA receptors selectively (and used for the treatment of NMDA-induced neurotoxicity after stroke or prolonged seizure activity) have the undesirable side effect of producing psychosis, perhaps by reducing the release of dopamine in the mesocortical pathway to the frontal lobe.

The existence of drugs that produce psychotic behavior by binding to the NMDA receptor indicates that psychotic behavior can probably be produced by interfering with several transmitter systems that act either in parallel or in combination with dopamine.

An Overall View

In considering the biological defect in schizophrenia we have focused on current insights into the molecular mechanisms of the disease and not on the social and psychological factors that act on an individual before, during, and even after they have the disease. In this context it is useful to take note of two common misconceptions.

First, it is sometimes thought that in classifying mental disorders we are classifying *people*; in reality, we are classifying *disorders* that people have. A person is not a schizophrenic—one *has* schizophrenia. Second, even though all the people with a particular mental illness are similar in ways that are important and all of these people will, by definition, share the *defining* features of the disease, the individuals who have the disease will

P.1207

likely differ in quite fundamental ways that may influence both the course and the outcome of the disease.

In addition to social factors, further research on schizophrenia needs to explore other contributing factors. A particularly important question is the genetic component, although genetic factors seem only to predispose people to schizophrenia. Another factor to consider is developmental abnormalities in the brain. In fact, schizophrenia is sometimes associated with what appears to be aberrant cell migration in both frontal and temporal lobes as well as with enlarged lateral ventricles, widening of cortical sulci, and reduced blood flow to the frontal lobes.

Dopaminergic agonists are capable of producing psychosis, and the affinity of antischizophrenic drugs for the dopaminergic D₂ and particularly the D₄ receptors is directly correlated with their clinical potency in alleviating psychotic symptoms. Postmortem studies have indeed found increases in the number of dopamine receptors in these limbic areas.

Indeed, almost all patients with schizophrenia show attentional and motivational deficits similar to those in patients with deficits in prefrontal cortex function. How this prefrontal defect relates to the defect in the mesolimbic dopaminergic projection is unclear. Initial clues to the answers for these questions may come from cloning one or more of the allelic variations of genes involved in schizophrenia.

Disorders of Mood: Depression, Mania, and Anxiety Disorders

Eric R. Kandel

MAKING THE DISTINCTION between a disturbance of cognitive faculties (a thought disorder) and a disturbance of emotion (a mood disorder) was an important step in the early development of the modern classification of mental illness. In clinical descriptions of emotional states the term *mood* refers to a sustained emotional state lasting weeks or more, while the term *affect* (or affective response) refers to immediate or momentary emotional state of a person. Affect is more directly responsive to external stimuli, although with significant mood disorders the range of affective responses is limited. Thus, affect is to mood as the weather (rainy or sunny) is to climate (tropical, moderate, or cold).

Normal affective responses serve important biological functions and range from euphoria to elation, pleasure, surprise, anger, anxiety, disappointment, sadness, grief, despair, and even depression. Three of these responses—euphoria, depression, and anxiety—can become so disordered, sustained, and dominant as to constitute a disease. We shall consider all three and discuss biological insights into these three disorders of mood. Although depression and euphoria (*mania*) have traditionally been referred to as disorders of affect, we use the more precise term mood. We shall then examine the anxiety states. Throughout we shall emphasize important interrelationships between the three mood disorders.

The Major Mood Disorders Can Be Either Unipolar or Bipolar

The most common mood disorder, unipolar depression, was described in the fifth century BC by Hippocrates. In the Hippocratic view moods were thought to depend on

P.1210

the balance of four humors—blood, phlegm, yellow bile, and black bile. An excess of black bile was believed to cause depression. In fact, the ancient Greek term for depression, *melancholia*, means black bile. Though this explanation of depression seems fanciful today, the underlying view that psychological disorders reflect physical processes is correct.

Modern efforts to update the Hippocratic formulation were, until very recently, hindered by a lack of precision in the classification of affective disorders. In his 1917 paper *Mourning and Melancholia*, Sigmund Freud wrote: "Even in descriptive psychiatry the definition of melancholia is uncertain; it takes on various clinical forms (some of them suggesting somatic rather than psychogenic affections) that do not seem definitely to warrant reduction to a unity." Only in the past two decades have relatively precise criteria for mood disorders been developed in parallel with those for cognitive disorders (see [Chapter 60](#)).

Unipolar Depression Is Most Likely Several Mood Disorders

The clinical features of unipolar depression are easily summarized. In Hamlet's words, "How weary, stale, flat, and unprofitable seem to me all the uses of this world!" Untreated, an episode of depression typically lasts 4-12 months. It is characterized by an unpleasant (*dysphoric*) mood that is present most of the day, day in and day out, as well as intense mental anguish, the inability to experience pleasure (*anhedonia*), and a generalized loss of interest in the world. The diagnosis also requires at least three of the following symptoms to be present: disturbed sleep (usually insomnia with early morning awakening, but sometimes oversleeping or hypersomnia), diminished appetite and loss of weight (but sometimes overeating), loss of energy, decreased sex drive, restlessness (psychomotor agitation), slowing down of thoughts and actions (psychomotor retardation), difficulty in concentrating, indecisiveness, feelings of worthlessness, guilt, pessimistic thoughts, and thoughts about dying and suicide. Other common symptoms, not required for diagnosis, are constipation, decreased salivation, and diurnal variation in the severity of symptoms, which are usually worse in the morning.

In addition to the inclusion criteria there are exclusion criteria; schizophrenia or other neurological diseases, for example, need to be excluded. There also should be no evidence of a recent death in the family or other traumatic events, since some of the symptoms of unipolar depression are also normal expressions of grief following trauma, personal loss, and mourning.

When the syndrome is defined in this manner, about 5% of the world's population have major unipolar depression. In the United States 8 million people at any given time are affected. Severe depression can be profoundly debilitating. In extreme cases patients stop eating or maintaining basic personal cleanliness. Although some people have only a single episode, usually the illness is recurrent. About 70% of patients who have one major depressive episode will have at least one more episode. The average age of onset is about 28 years, but the first episode can occur at almost any age. Indeed, depression also affects young children but is often unrecognized in them. Depression also occurs in the elderly; in fact, older people who become depressed often have not had an earlier episode. Women are affected about two to three times more often than men.

Unipolar depression is most likely not a single illness but a group of disorders. However, the attempt to distinguish three subtypes has been only partially successful so far. The subtypes that are commonly distinguished are melancholic depression, atypical depression, and dysthymia.

Melancholic depression represents the clearest subtype among the major depressions and accounts for 40-60% of people treated for unipolar depression. Because it often has no obvious external precipitating cause—no personal loss or rejection or obvious change in life events—it was formerly referred to as *endogenous depression*. The disorder is characterized by six symptoms: (1) depression with diurnal variations in mood (worse in the morning), (2) insomnia with early-morning wakening, (3) anorexia with significant weight loss, (4) psychomotor agitation and mental pain, (5) loss of interest in almost all activity and lack of response to pleasurable stimuli, and (6) when severe, a complete loss of the capacity for joy (anhedonia).

Patients with melancholic depression often have a history of one or more previous episodes of major depression with recovery. Many patients show characteristic abnormalities in sleep pattern, as measured by electroencephalography. These abnormalities occur primarily during the first half of the night, when the latency for the rapid eye movement (REM) phase of sleep is shortened. More than half of patients with melancholic depression have frequent awakenings. Melancholic depression sometimes leads to psychomotor retardation, to emotional or intellectual underactivity (*retardation*). At other times there is a rather painful state of agitation and an active and persistent preoccupation with perceived deficiencies and inadequacies of one's character. Patients with melancholic depression tend to respond preferentially to electroconvulsive therapy (ECT), tricyclic antidepressants, and selective serotonin reuptake inhibitors.

Atypical depression is slightly less common than melancholic depression; accounting for about 15% of

P.1211

patients hospitalized for major mood disorders. The disease is called atypical because symptoms are the opposite of melancholic depression: it first appears earlier in life and tends to be chronic rather than phasic. In addition, unlike patients with melancholic depression, patients with atypical depression cheer up temporarily when good things happen. Finally, patients with atypical depression do not have loss of appetite and weight loss but instead overeat and gain weight; they do not report insomnia but rather tend to sleep more; and their depression is worse, not better, in the evening. The patients also have prominent symptoms of anxiety. Patients with atypical depression tend to respond preferentially to monoamine oxidase inhibitors.

Finally, *dysthymia* is a persistent but milder depression lasting for at least two years with symptoms that fall short of the criteria of a major depression.

It is important to appreciate that we *normally* experience grief or despondency after loss of a family member, and this normal mourning can involve any of the individual symptoms of atypical or melancholic depression. Perhaps the most important distinction between bereavement and depression is that bereavement is

rarely associated with persistent functional impairment. In addition, despondent or grief-stricken people have fewer suicidal thoughts and, more important, they have lower rates of suicide than patients with atypical or melancholic depression.

Most helpful in making a diagnosis of depression, however, is the finding of *reactive affect*. Unlike major depression, the depression normally experienced after a personal loss is not unrelenting and pervasive—it *does not persist every day, all day*. Two or three months after a personal loss, most people are able to experience and react to moments of pleasure and contentment that relieve the sadness, something a person with a major depression cannot do. Finally, normal mourning tends to remit after several months. It does not persist. When mourning does persist it usually reflects a transition to an episode of major depression, a transition that occurs in individuals with a genetic predisposition.

Bipolar Depressive (Manic-Depressive) Disorders Give Rise to Alternating Euphoria and Depression

About 25% of patients with major depression (or two million people in the United States) will also experience a manic episode, if only a mild one. Patients who experience both depressive and manic episodes have a distinct disorder called *bipolar mood disorder*. The illness affects men and women equally, and the average age of onset of the first episode is a decade younger than that of unipolar depression (the onset usually occurs at age 20 rather than 30).

Figure 61-1 The incidence of bipolar and unipolar depression is higher among first-degree relatives of patients who have either disease than in the general population. (From [Barondes 1993](#).)

Episodes of depression in bipolar disorders are clinically similar to those of the unipolar type. The manic episodes are characterized by an elevated, expansive, or irritable mood lasting at least one week, together with several of the following symptoms: over-activity, over-talkativeness (pressure of speech), social intrusiveness, increased energy and libido, flight of ideas, grandiosity, distractibility, decreased need for sleep, and reckless spending. In severe cases patients are delusional and hallucinate. Most episodes have no detectable psychosocial precipitant

Bipolar disorder is typically recurrent. After an initial episode of euphoria, subsequent episodes of either depression or euphoria are likely to occur about twice as often in bipolar disorder as in unipolar disease. One of the most striking features of bipolar illness is that a subset of patients (*rapid cyclers*) may switch from depression to euphoria or vice versa quite rapidly, sometimes in a matter of minutes. Depression tends to become more pronounced with age and recur with greater frequency.

Mood Disorders Have a Strong Genetic Predisposition

As in schizophrenia, genetic factors are important in both unipolar and bipolar mood disorders. The morbidity rate of depression is modestly higher in first-degree relatives (parents, siblings, and children) of patients

P.1212

with depressive illness than in the general population ([Figure 61-1](#)). The overall concordance rate for monozygotic twin pairs with bipolar depression may reach 80%; the rate for dizygotic twins is approximately 10% (the same as for siblings).

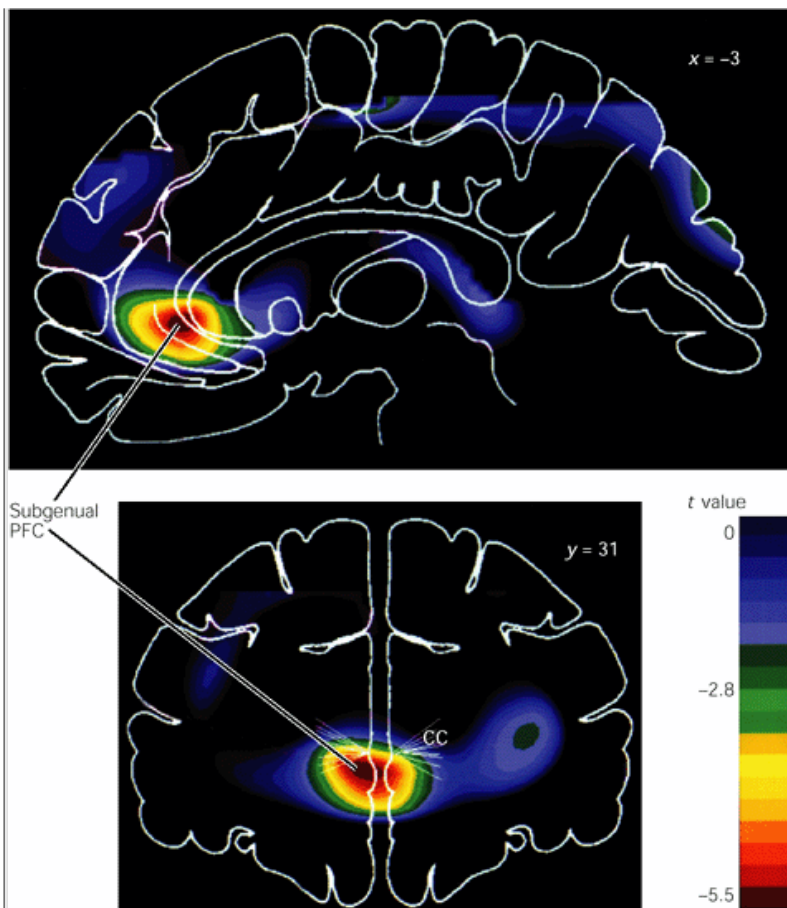

Figure 61-2 Some patients with unipolar and bipolar disease show a functional abnormality in the prefrontal cortex ventral to the genu of the corpus callosum. During the depressive phase of the bipolar disease activity is decreased, while during the manic phase it is increased. The two images show a decrease in metabolism in patients with depression relative to controls. Both phases of the illness localize to the agranular region of the anterior cingulate gyrus ventral to the corpus callosum. Anterior, or left, is to the left. (From [Drevets et al. 1997.](#))

Seymour Kety, Paul Wender, and David Rosenthal extended their studies of patterns of schizophrenia in the families of adoptees ([Chapter 60](#)) to include manic-depressive disorders. They found that the rate of mood disorders among the biological parents of adoptees with depressive or manic-depressive illness was higher than among the adoptive parents (and higher than the rate among biological and adoptive parents of mentally healthy adoptees). Particularly impressive was the finding that the incidence of suicide among biological relatives of adoptees with depressive illness was six times higher than among the biological relatives of normal adoptees. Furthermore, the concordance rate of affective illness in monozygotic twins reared apart is 40-60%, similar to the concordance in those reared together.

These concordance rates for unipolar and bipolar depression in monozygotic twin pairs indicate that, like schizophrenia, major depression is polygenic. Several genes are likely to be involved, each making a small contribution. Nongenetic factors are also likely to be important in determining whether an affective disorder is expressed. Their importance is reflected in two important secular trends in depression over the past 50 years. Since 1940 the age of onset has become younger (28 years rather than 35), and the incidence of depression in the families of patients has increased. Perhaps people vulnerable to depression are now more likely to become depressed than they were half a century ago because of the increased stress of everyday life. In addition there may also be a genetic anticipation

Genetic linkage analysis (see [Chapter 3](#)) has led to the identification of several loci that might contribute to affective illness. Although no specific gene has yet been identified, one locus on chromosome 18 (18q22-23) has the strongest supporting evidence.

Familial Unipolar and Bipolar Depressions May Reflect an Abnormality in the Functioning of the Subgenual Region of the Frontal Cortex

Positron emission tomography (PET) scanning and functional magnetic resonance imaging (fMRI) studies have recently defined a potential anatomical abnormality in P.1213

the prefrontal cortex ventral to the genu in the corpus callosum that is affected in familial cases of unipolar and bipolar depression. During the depressive phase of the illness, activity in this region is decreased in patients who have either unipolar or bipolar depression. This decrease seems to be accounted for in large part by a reduction in the volume (by about 45%) of the gray matter of this part of the prefrontal cortex. In contrast, in patients with bipolar disease this region shows an increase in activity during the manic phase of the illness.

A Monoamine oxidase inhibitors

Phenzelzine

Isocarboxazid

B Biogenic amine uptake blockers (tricyclic antidepressants)

Imipramine

Amitriptyline

C Selective serotonin reuptake blockers

Fluoxetine HCl

Figure 61-3 The three types of antidepressants.

A. Clinically useful monoamine oxidase inhibitors are chemically diverse. These drugs are thought to act by decreasing the breakdown of biogenic amines in the brain, thereby making more neurotransmitter available for release at aminergic synapses and prolonging the action of the aminergic transmitters. The antidepressant effects of the drugs take several weeks to fully develop.

B. Tricyclic antidepressant drugs (see [Figure 61-6](#)) have immediate and long-term effects. Blockage of the reuptake of biogenic amine neurotransmitters from the synapse is evident soon after administration. The therapeutic action of antidepressants usually begins 4 days to 3 weeks after starting the medication.

C. Selective serotonin reuptake inhibitors are the most easily tolerated antidepressants.

This finding is of interest because other clinical studies as well as studies in experimental animals have shown that the subgenual region of the prefrontal cortex is important for mood states ([Figure 61-2](#)). This region of the prefrontal cortex has extensive connections with other regions involved in emotional behavior, such as the amygdala, the lateral hypothalamus, the nucleus accumbens, and the noradrenergic, serotonergic, and dopaminergic systems of the brain stem ([Chapter 50](#)). People who have lesions in this area have difficulty experiencing emotion and have abnormal autonomic responses to emotionally arousing stimuli. Moreover, lesions in this area severely compromise the ability to reason and make intelligent, rational decisions. Conversely, Antonio Damasio and his colleagues have observed that small irritative lesions in this region cause episodes of anger and aggressive behavior.

Unipolar Depressive and Manic-Depressive Disorders Can Be Treated Effectively

There are four effective treatments for unipolar and bipolar illnesses: electroconvulsive therapy (ECT), antidepressant drugs, lithium, and anticonvulsants. Of the four, ECT has been used for the longest period of time, over 50 years. Although antidepressants are generally the first choice in the treatment of major depression, ECT is very effective. It produces full remission or marked improvement in about 85% of patients with well-defined major depression.

The critical therapeutic factor in ECT is the induction of a generalized brain seizure. Since the motor component of the seizure is not necessary for therapeutic results, modern ECT is always given under anesthesia with complete muscle relaxation. On average, six to eight treatments given at two-day intervals over a period of 2-4 weeks usually suffice to produce a complete remission of symptoms. As might be predicted from our knowledge of seizure activity ([Chapter 46](#)), ECT creates

P.1214

many temporary changes in brain functions. Although the therapeutic mechanism of ECT is not understood, it may be related to changes in aminergic receptor sensitivity, as we shall see later.

A Pathways

B Targets

Figure 61-4 The major serotonergic pathways arise in the raphe nuclei. (Adapted from Heimer 1995.)

A. Lateral view of the brain illustrates that the raphe nuclei form a fairly continuous collection of cell groups close to the midline throughout the brain stem. For clarity, they are illustrated here in distinct rostral and caudal groups. The rostral raphe nuclei project to a large number of forebrain structures (fibers that project laterally through the internal and external capsules to the neocortex are not shown here).

B. This coronal view of the brain illustrates some of the major targets of the serotonergic raphe nuclei neurons.

The most widely used antidepressant drugs fall into three major classes:

- *Monoamine oxidase inhibitors*, such as phenelzine (Figure 61-3A). These were the first effective antidepressants to be used clinically but are now used only infrequently.
- *Tricyclic compounds*, or general reuptake inhibitors of biogenic amines, such as imipramine, are so named for their three-ring molecular structure (Figure 61-3B). These compounds inhibit the uptake of both serotonin and norepinephrine and are probably the most effective drugs for patients who are severely depressed.
- *Selective serotonin reuptake inhibitors*, such as fluoxetine (Prozac) (Figure 61-3C), paroxetine (Paxil), and sertraline (Zoloft). These are the most commonly used antidepressants, and they work by selectively inhibiting the uptake of serotonin. They are most commonly used for patients who are only moderately depressed. These are, after the tricyclic compounds, the most commonly used drugs in severely ill patients.

The monoamine oxidase inhibitors and the tricyclic antidepressants produce remission or marked improvement in about 70% of patients with major depressions. When optimal doses are given, the success rate with tricyclic drugs and the specific serotonin reuptake inhibitors may reach 85%, almost as effective as ECT. Patients with bipolar depression occasionally become manic during treatment with either class of antidepressant drugs. Although a few patients with bipolar disease begin to improve immediately, there usually is a lag of 1-3 weeks before the symptoms of depression begin to improve, and 4-6 weeks are generally required for a full response.

Table 61-1 Serotonin Receptors

Receptors	Gene family
Receptors linked to second-message systems 5-HT _{1A} linked to inhibition of adenylyl cyclase 5-HT _{1B} linked to inhibition of adenylyl cyclase 5-HT _{1D} linked to inhibition of adenylyl cyclase 5-HT _{1E} linked to inhibition of adenylyl cyclase 5-HT _{1F} linked to inhibition of adenylyl cyclase 5-HT _{2A} linked to phospholipase and PI turnover 5-HT _{2B} linked to phospholipase and PI turnover 5-HT _{2C} linked to phospholipase and PI turnover 5-HT ₄ linked to stimulation of adenylyl cyclase 5-HT ₅ unknown linkage 5-HT ₆ linked to stimulation of adenylyl cyclase 5-HT ₇ linked to stimulation of adenylyl cyclase	Superfamily of receptors with seven transmembrane regions coupled to G proteins
Receptors linked to an ion channel 5-HT ₃	Superfamily of ligand-gated ion channels

5-HT = 5-hydroxytryptamine (serotonin); PI = Phosphatidylinositolide.

Figure 61-5 The noradrenergic pathways arise in the locus ceruleus. (Adapted from Heimer 1995.)

A. A lateral mid-sagittal view demonstrates the course of the major noradrenergic pathways from the locus ceruleus and lateral brain stem tegmentum. The pigmented locus ceruleus, located immediately beneath the floor of the fourth ventricle in the rostralateral pons, is the best understood noradrenergic nucleus in the brain. Its projections reach many areas in the forebrain, cerebellum, and spinal cord. Noradrenergic neurons in the lateral brain stem tegmentum innervate several structures in the basal forebrain, including the hypothalamus and the amygdaloid body.

B. A coronal section shows the major targets of neurons from the locus ceruleus. (Adapted from Heimer 1995.)

Type	Second-messenger system	Location
β_1	Linked to stimulation of adenylyl cyclase	Cerebral cortex, cerebellum
β_2	Linked to stimulation of adenylyl cyclase	Cerebral cortex, cerebellum
α_1	Linked to phospholipase C, PI, PKC, DAG, Ca^{2+} in peripheral tissues	Brain, blood vessels, spleen
α_2	Linked to inhibition of adenylyl cyclase	Presynaptic nerve terminals throughout the brain

PI = Phosphatidylinositide; PKC = Protein kinase C; DAG = Diacylglycerol.

P.1215

P.1216

Lithium salts, first reported in the psychiatric treatment of manic-depressive illness in 1949 by John Cade, are effective in terminating manic episodes and are used as mood stabilizers. Moreover, maintenance therapy with lithium is of significant prophylactic value in preventing or attenuating recurrent manic and, to a lesser extent, depressive episodes. Lithium is rarely used by itself for treatment of unipolar depression. However, it is frequently used in conjunction with monoamine oxidase inhibitors, tricyclic compounds, or selective serotonin reuptake inhibitors to augment the response of these conventional antidepressants (see Figure 61-9).

Drugs effective as anticonvulsants (such as sodium valproate and carbamazepine) are also used as mood stabilizers and are quite effective in reducing psychotic symptoms in acute mania or severe depression. Antipsychotic drugs (Chapter 60) are also used frequently in combination with tricyclic drugs, and even with ECT when depression is accompanied by delusions and hallucinations.

Drugs Effective in Depression Act on Serotonergic and Noradrenergic Pathways

Drugs effective in treating depression act primarily on the serotonergic and noradrenergic systems of the brain (Chapter 45). The evidence is particularly impressive for serotonin—all selective serotonin reuptake inhibitors tested have been found to be effective against depression. The action of these drugs, therefore, provides the first clues to a neurochemical basis of depressive disorders. The major serotonergic pathways have their origin in the raphe nuclei in the brain stem (Figure 61-4). Cells from the rostral parts of these nuclei project to the forebrain; single serotonergic neurons project to hundreds of target cells in a large, diffuse distribution. (The cells of the caudal part of the raphe nuclei project to the spinal cord.)

The serotonergic receptors are traditionally classified into at least seven major types. Some types decrease adenylyl cyclase, some increase adenylyl cyclase, others are coupled to phosphatidylinositide turnover, and still others are ligand-gated ion channels (Table 61-1).

The noradrenergic pathways originate in the locus ceruleus (Figure 61-5). The axons of some locus ceruleus neurons ascend to innervate the hypothalamus and all regions of the cerebral cortex, including the hippocampus. Other neurons have descending axons that reach the dorsal and ventral horns of the spinal cord. Like serotonergic cells, noradrenergic neurons innervate broad areas and act on a number of receptor types (Table 61-2). Certain components of the noradrenergic system appear to be involved with arousal and fear (Chapter 50), while others are thought to be involved, together with the mesolimbic components of the dopaminergic system, in positive motivation and pleasure (Chapter 51). The pervasive anxiety and loss of pleasure characteristic of melancholia and atypical depression might therefore be related to dysregulation of these two components of the noradrenergic system.

An Abnormality in Biogenic Amine Transmission May Contribute to the Disorders of Mood

Norepinephrine is synthesized from tyrosine, and serotonin from tryptophan (Chapter 15). The transmitters are packaged in synaptic vesicles and released into the synaptic cleft by means of exocytosis when the neuron fires an action potential. Both norepinephrine and serotonin interact with postsynaptic receptors, and this activity is limited by active reuptake of the released transmitter into the presynaptic terminals as well as into glial cells. Inside the presynaptic terminals the transmitters are packaged again into vesicles or catabolized primarily by the mitochondrial enzyme monoamine oxidase.

Until recently the consensus view—expressed first in the *catecholamine hypothesis* and then in the more general *biogenic amine hypothesis*—was that depression represented

P.1217

a decreased availability of either norepinephrine or serotonin or both. Mania was believed to result from the over-activity of noradrenergic systems. This hypothesis was derived from studies of the effects of various drugs on the serotonergic and noradrenergic systems of the brain. The idea originally came from the observation in 1950 that reserpine, a Rauwolfia alkaloid then used extensively in the treatment of hypertension, precipitated depressive syndromes in about 15% of treated patients. Reserpine also produced a depression-like syndrome, with motor retardation and sedation, in animals. Bernard Brodie and his colleagues found that reserpine depletes the brain of serotonin and norepinephrine (as well as dopamine) by inhibiting the uptake of the transmitter into synaptic vesicles in the presynaptic cell, thereby keeping the transmitter in the cytoplasm, where it undergoes degradation by monoamine oxidase (Figure 61-6).

Table 61-3 Effects of Long-Term Administration of Antidepressant Drugs on the Serotonergic System

Antidepressant treatment	Responsiveness of somatodendritic of 5-HT _{1A} autoreceptors	Function of terminal 5-HT autoreceptors	Function of terminal α_2 adrenergic receptors	Responsiveness of postsynaptic receptors	Net serotonin transmission 5-HT receptors
Selective serotonin reuptake inhibitors	Decreased	Decreased	NC	NC	Increased
Monoamine oxidase inhibitors	Decreased	NC	?	NC or decreased	Increased
5-HT _{1A} receptor agonists	Decreased	NC	ND	NC	Increased
Tricyclic antidepressants	NC	NC	ND	Increased	Increased
Electroconvulsive shocks	NC	NC	NC	Increased	Increased

From Blier and deMontigny 1994; NC = no change; ND = no data; 5-HT = 5-hydroxytryptamine (serotonin).

Monoamine oxidase inhibitors, such as isoniazid, were later found to be effective antidepressants. Isoniazid was initially developed in the 1950s to treat tuberculosis. In the course of clinical trials it was noted that some patients who had depression as well as tuberculosis experienced elevations in mood when treated with the drug. Isoniazid was next tried in patients with depression who did not have tuberculosis and was found to be effective. Monoamine oxidase inhibitors increase the concentration of serotonin and norepinephrine in the brain by reducing the degradation of these transmitters by monoamine oxidase. In experimental animals monoamine oxidase inhibitors prevent reserpine's sedative effects on behavior as well as its degradation of cytoplasmic monoamines.

Further support for the view that monoamine oxidase inhibitors act therapeutically by increasing the availability of serotonin and biogenic amines came with the discovery of a second class of effective antidepressants: the tricyclics. These agents *block* the active reuptake of serotonin and norepinephrine by presynaptic neurons, thereby prolonging the action of these transmitters in the synaptic cleft (see Figure 61-6). Finally, the third group of compounds that proved to be effective in depression, the selective serotonin reuptake inhibitors, affect *only* serotonin and not norepinephrine. Thus, all three major classes of antidepressants maximize synaptic transmission of serotonin by inhibiting the reuptake of the transmitter or its degradation (Table 61-3). Even electroconvulsive shock increases serotonergic transmission (Table 61-3). It does so by increasing the sensitivity of the 5-HT_{1A} receptors in the hippocampus and increasing the number of 5-HT_{2A} receptors.

The remarkable effectiveness of selective serotonin reuptake inhibitors on depression provides the most compelling evidence that enhancement of serotonergic transmission underlies the therapeutic response to some antidepressant treatments. However, the biogenic amine hypothesis fails to account for a number of important clinical phenomena. In particular, it fails to explain why the clinical response to all antidepressant drugs is so slow after administration of the drugs, whereas the tricyclic agents and the selective serotonin reuptake inhibitors rapidly block the high-affinity reuptake

P.1218

P.1219

systems. This blockade is much more rapid than the clinical response. If the clinical response is a result of an increase in serotonergic synaptic transmission, what accounts for the delay in the response? In addition, the tricyclic drugs vary widely in their relative abilities to block serotonin or norepinephrine reuptake, yet their clinical efficacy in patients with depression is about the same. Finally, in some patients with depression the onset of the illness is associated not with a decrease but with an *increase* in the level of norepinephrine in spinal fluid and plasma, and treatment leads to reduction to a normal level.

Figure 61-6 (Opposite) Action of antidepressant and other drugs at serotonergic and noradrenergic synapses.

A. Antidepressant and other drugs have five possible sites of action at serotonergic synapses.

1. Enzymatic synthesis. Both *p*-chlorophenylalanine and *p*-propyldopacetamide can effectively inhibit the enzyme tryptophan hydroxylase, which converts tryptophan to 5-OH-tryptophan, the precursor of 5-hydroxytryptophan (5-HT, serotonin).

2. Storage. Reserpine and tetrabenazine interfere with the reuptake-storage mechanism of the amine granules, causing a marked depletion of serotonin.

3. Receptor interactions. These fall into two categories. **a.** Autoreceptor 8-hydroxy-diprolamino-tetraline (8-OH-DPAT) is an agonist of the 5-HT autoreceptor. **b.** Lysergic acid diethylamide (LSD) acts as a partial agonist at postsynaptic serotonergic receptors in the central nervous system. A number of specific compounds are now candidates to act as receptor-blocking agents at various serotonergic synapses.

4. Reuptake. Tricyclic drugs with a tertiary nitrogen, such as imipramine and amitriptyline, inhibit the reuptake of serotonin into the presynaptic terminal and thus increase the efficacy of transmission. Fluoxetine and sertraline are even more selective inhibitors of serotonin uptake.

5. Degradation by monoamine oxidase (MAO). Iproniazid and clorgyline are effective inhibitors of MAO, which is localized in the outer membrane of mitochondria and can degrade serotonin present in a free state within the presynaptic terminal. **5-HIAA** = 5-hydroxyindoleacetic acid.

B. Antidepressants and other drugs have seven possible sites of action at noradrenergic synapses.

1. Enzymatic synthesis. **a.** The competitive inhibitor α -methyltyrosine blocks the reaction catalyzed by tyrosine hydroxylase. **b.** A dithiocarbamate derivative, FLA 63, blocks the reaction catalyzed by dopamine β -hydroxylase, which converts DOPA to dopamine.

2. Storage. Reserpine and tetrabenazine interfere with the reuptake-storage mechanism of the amine granules. The depletion of norepinephrine (NE) by reserpine is long-lasting and the storage granules are irreversibly damaged, causing permanent depletion of NE available for release transmission. Tetrabenazine also interferes with the reuptake of free cytoplasmic NE into the granules.

3. Release. Amphetamine appears to cause an increase in the net release of NE, most likely because of its ability to block the reuptake.

4. Receptor interaction. **a.** Clonidine is a very potent α -receptor agonist. **b.** Phenoxybenzamine and phentolamine are effective α -receptor blocking agents. Recent

experiments have indicated that these drugs also have a presynaptic site of action.

5. Degradation by COMT. Tropolone inhibits COMT, which inactivates NE. COMT is believed to be localized outside the postsynaptic neuron.

6. Reuptake. The tricyclic drug desipramine is a potent inhibitor of the reuptake of NE into the presynaptic terminal. As a result, NE remains in the synapse longer and has a greater postsynaptic effect.

7. Degradation by monoamine oxidase (MAO). Pargyline is an effective inhibitor of MAO, which appears to be localized in the outer membrane of mitochondria and can degrade the NE present in a free state within the presynaptic terminal. Normetanephrine (NM) is formed by the action of the enzyme catechol O-methyltransferase (COMT) on NE.

Some clues are emerging that may help to resolve these issues. For example, it is now clear that antidepressants affect processes other than the reuptake and accumulation of serotonin. In addition to their rapid biochemical effects on reuptake, both monoamine oxidase inhibitors and tricyclic antidepressants produce a delayed but long-term increase in the sensitivity of serotonin receptors. Conversely, the selective serotonin reuptake inhibitors produce a delayed decrease in the sensitivity of 5HT_{1A} and 5HT_{1B} inhibitory autoreceptors present on many serotonergic cells, leading to increased release of serotonin. Both of these actions lead to a slow increase in the effectiveness of serotonergic synaptic transmission.

Given these findings, where does the biogenic amine hypothesis stand? The initial, simple form of the biogenic amine hypothesis, which states that reduction of biogenic amines leads to depression and elevation to mania, is no longer valid. There probably is no simple relationship between biogenic amines and depression. If a relationship exists at all, which seems likely, it is complicated by three factors.

First, the subtypes of major depression are most likely not single disorders, but a group of disorders with several underlying pathologies. Second, disturbances in one of several transmitter systems can lead to depression. Finally, the various modulatory systems of the brain—the serotonergic, dopaminergic, and adrenergic systems—do not function independently of each other but rather interact at several levels. Specifically, the distribution of the serotonergic system overlaps with and interacts with the noradrenergic system. Moreover, receptors for the two amines coexist on the same neurons, and there is cross-talk between second messengers activated by these transmitters. Long-term administration of antidepressants fails to downregulate the β -adrenergic receptors when serotonergic systems have been eliminated experimentally.

In addition, antidepressants act on the cholinergic and GABA-ergic systems. Cholinergic neurons excite the noradrenergic cells of the locus ceruleus through P.1220

muscarinic receptors, and cholinergic agonists can induce depression. Indeed, patients with a history of depression tend to be hyperresponsive to cholinergic agonists, even when their mood is normal.

Figure 61-7 The exact therapeutic action of lithium, used to treat bipolar depression, is unknown. However, lithium has been shown to affect the phosphoinositide second-messenger system. Many synaptic receptors act through a G protein to mediate the conversion of phosphoinositide diphosphate (PIP₂), a membrane lipid, into diacylglycerol (DAG) and inositol triphosphate (IP₃). IP₃ is further broken down to inositol phosphate (IP), which is then converted to free inositol by the enzyme inositol-1-phosphatase. Lithium blocks this enzyme and therefore reduces the responsiveness of these neurons by causing IP₃ to accumulate in the cytoplasm. The roles of IP₃ and protein kinase C are discussed in [Chapter 13](#).

Since most serotonergic and adrenergic receptors act on second-messenger pathways—activating or inhibiting adenylyl cyclase or stimulating phosphoinositide turnover—it is perhaps not surprising that drugs acting directly on these pathways are now being developed. For example, lithium salts, which are highly effective in bipolar disorder, block the enzyme inositol-1-phosphatase, which recycles inositol triphosphate back to inositol. This results in a buildup of inositol 1,4,5-triphosphate (IP₃), which is known to be active in regulating intracellular Ca²⁺ levels. Inhibition of this enzyme is thought to reduce the responsiveness of those neurons with transmitter receptors coupled to the IP₃ pathway ([Figure 61-7](#)). This could be the way lithium acts therapeutically, perhaps by dampening excessive neural activity in mania.

Unipolar Depression May Involve Disturbances of Neuroendocrine Function

As first pointed out by Edward Sachar, depression is associated with clinical signs of hypothalamic disturbance. The best-understood hypothalamic disturbance in severe depression is neuroendocrine and is reflected in excessive secretion of adrenocorticotropic hormone (ACTH) by the pituitary, leading to excessive secretion of cortisol from the adrenal cortex. The hypersecretion of ACTH is so great that enlargement of the adrenal gland can be detected on computerized axial tomography (CAT) scans of some patients with depression.

In normal people the secretion of cortisol follows a circadian rhythm; secretion peaks at 8:00 AM and is relatively lower in the evening and early morning hours. This circadian cycle is disturbed in about one-half of patients with depression, who secrete excessive amounts of cortisol throughout the day ([Figure 61-8](#)). The disturbance is not dependent on stress and is not found in other psychiatric disorders. Cortisol secretion returns to normal with recovery.

Philip Gold and his colleagues found that the increased secretion of cortisol results from hypersecretion of corticotropin-releasing hormone (CTRH) from the hypothalamus, and that the level of CTRH correlates positively with depression. Release of CTRH is stimulated by norepinephrine and acetylcholine, and release of CTRH induces anxiety in experimental animals. Thus, Gold and his colleagues have suggested that CTRH and the noradrenergic system may reinforce one another.

Hypersecretion of cortisol is sometimes resistant to feedback suppression by the potent synthetic corticosteroid dexamethasone, which depresses secretion of adrenocorticotropic hormone. The *dexamethasone suppression test* has been used to diagnose depression because in at least 40% of rigorously diagnosed patients with depression hypersecretion of cortisol is resistant to feedback suppression by dexamethasone. However, the test is not specific; dexamethasone suppression is also abnormal in patients who have dementia, anorexia nervosa, bulimia, alcohol withdrawal, or weight loss.

There Are at Least Four Major Types of Anxiety Disorders

Just as grief is a normal response to personal loss, anxiety is a normal response to threatening situations. Perceived threats that generate anxiety may be active and direct or indirect, such as the absence of people or objects

P.1221

that represent security. Anxiety is adaptive; it signals potential danger and can contribute to the mastery of a difficult situation and thus to personal growth. Excessive anxiety, on the other hand, is maladaptive, either because it is too intense or because it is inappropriately provoked by events that present no real danger. Thus, anxiety is pathological when excessive and persistent, or when it no longer serves to signal danger.

The key feature of anxiety disorders is increased fearfulness accompanied by subjective as well as objective manifestations. The subjective manifestations range from a heightened sense of awareness to a deep fear of impending disaster and death. The objective manifestations are a racing heart, avoidance behavior and signs of restlessness, heightened responsiveness, palpitations, tremor, sweating, increased blood pressure, dry mouth, and a desire to run or escape. Depression and anxiety often occur together.

Anxiety disorders are the most common psychiatric disorders, found in 10-30% of the general population. Anxiety disorders can be subdivided into several types based on clinical characteristics and response to psychopharmacologic agents. These major categories include panic disorder, post-traumatic stress disorder, (PTSD), generalized anxiety disorder, social phobia, and obsessive-compulsive disorder (OCD).

Panic Attacks Are Brief Episodes of Terror

Panic attacks are brief, recurrent, unexpected episodes of terror without a clearly identifiable cause. The attacks are usually brief, most commonly lasting 15-30 minutes; occasionally, but only rarely, they last up to an hour. An essential feature of these attacks is that they are *unexpected*. They do not occur in situations that normally evoke fear or in which the patient is the focus of other people's attention. The attacks are characterized by a sense of impending doom accompanied by an intense over-activity of the sympathetic nervous system (referred to as a *sympathetic crisis*): The heart races, there is shortness of breath; dizziness; trembling or shaking of the hands and legs; flushes or chills; chest pain; and fear of dying, or of going crazy, or of doing something uncontrolled. Shortness of breath is characteristic of panic attacks but not of the acute terror evident in battle, suggesting that panic attacks may represent a false alarm for suffocation.

Figure 61-8 Many patients with depression secrete excess ACTH and cortisol during the day. In normal subjects there is a circadian rhythm to the secretion, which peaks at 8:00 AM and then decreases progressively from the early morning hours into the evening until 3:00 AM at night (0300). By contrast, in depressed patients the plasma cortisol concentration is elevated throughout much of the 24-hour period of the day, with only a slight decline in the evening (2000 to 0200). The plot shows the mean hourly plasma cortisol concentration over a 24-hour period for seven patients with unipolar depression compared with the mean for 54 normal subjects. Each point represents the mean cortisol concentration every 60 minutes.

When panic attacks recur the resulting syndrome is called *panic disorder*. Attacks recur over a period ranging from months to several years and are often experienced several times a week. Panic disorders usually begin in adolescence.

An interesting aspect of panic attacks is that they can be induced in some patients who have this disorder, but not in most normal subjects, by the infusion of sodium lactate into the blood or the inhalation of carbon dioxide. Thus, sodium lactate infusion provides an approach for studying the mechanism underlying this disorder because the onset of an attack can be timed precisely. Moreover, regular use of antidepressants that are effective against spontaneous panic attacks also prevent the panic induced by the infusion. Similarly, yohimbine, a drug that activates central noradrenergic neurons (by blocking the α_2 adrenergic receptors that serve as inhibiting autoreceptors), precipitates panic attacks in patients but not in normal subjects, indicating that panic attacks involve an abnormality in the biogenic amine system of the brain.

A significant proportion of patients with panic disorders have a genetic predisposition. Half of patients

P.1222

with panic attacks also have depression, a finding that has led to the suggestion that panic attacks may be a variant of depressive illness or a precursor to it. This is consistent with the initially surprising finding that panic disorder is successfully treated with both tricyclic antidepressants and monoamine oxidase inhibitors. Now that more is known about the function of the locus ceruleus, this finding is perhaps less surprising. The noradrenergic cells in this nucleus respond most effectively to stimuli that produce intense fear. In fact, cognitive therapy for panic attacks trains patients not to act on their autonomic signals.

Post-Traumatic Stress Disorder Reflects Persistent Traces of Anxiety That Follow Traumatic Episodes

An interesting variant of panic attacks is *post-traumatic stress disorder*. Although now appreciated as fairly common, this disorder was not clearly recognized in its present form until the 1980s. Post-traumatic stress disorder occurs in people after an extremely stressful event, such as life-threatening combat or physical abuse. It is manifested in recurrent episodes of fear, often triggered by reminders of the initial trauma. One of the most striking features of this disorder is that the memory for the traumatic experience remains powerful for decades and is readily reactivated by a variety of stimuli and stressors. This is thought to be due to the recruitment of the noradrenergic system by these reactivating stimuli. As we shall learn in [Chapter 63](#), biogenic amines are important in modulating various memory processes.

Vietnam War veterans with post-traumatic stress disorder show heightened noradrenergic functioning. They excrete high levels of norepinephrine in their urine, presumably reflecting high circulating catecholamine levels. When exposed to gunfire or other stimuli associated with combat, these veterans respond with dramatic increases in blood pressure and heart rate. When patients with post-traumatic stress disorder are given yohimbine, they experience a type of panic attack: An intense memory is accompanied by autonomic symptoms (increase in blood pressure and heart rate) and an increase in the core symptoms, such as frightening thoughts, emotional numbing, and grief.

These manifestations are all consistent with the idea that uncontrollable stress produces substantial increases in noradrenergic functioning in the brain. Propranolol and clonidine, which act to decrease noradrenergic transmission, greatly ameliorate the symptoms of post-traumatic stress disorder. Interestingly, a large percentage (about 50%) of patients with post-traumatic stress disorder also show a concurrent panic disorder.

Generalized Anxiety Disorder Is Characterized by Long-Lasting Worries

The key feature of generalized anxiety disorder is unrealistic or excessive worry, lasting not minutes but continuously for six months or longer. The symptoms are motor tension (trembling, twitching, muscle aches, restlessness), autonomic hyperactivity (palpitations, increased heart rate, sweating, cold hands), and vigilance and scanning (feeling on edge, exaggerated startle response, difficulty in concentrating). The disorder sometimes follows an episode of depression.

One group of drugs that is particularly effective in treating generalized anxiety disorder is the benzodiazepines, such as chlordiazepoxide (Librium) and its derivative, diazepam (Valium). Benzodiazepines produce their therapeutic effect by enhancing the activity of the GABA_A receptor. GABA is the major inhibitory transmitter in the brain (Chapter 12). The GABA_A receptor opens Cl⁻ channels and the resulting influx of Cl⁻ hyperpolarizes and thus inhibits target cells. Benzodiazepine increases the affinity of the receptor for GABA, resulting in an increase in Cl⁻ influx through the Cl⁻ channels and thereby prolonging the synaptic inhibition produced by GABA (Figure 61-9).

The GABA_A receptor has separate binding sites for GABA, barbiturates, and benzodiazepines (Chapter 11). The protein is allosteric; binding of any one of the three ligands (GABA, benzodiazepine, or barbiturate) influences the binding of the other two and facilitates GABA's action. In particular, GABA will bind more tightly when a benzodiazepine also is bound to its site on the receptor. Nevertheless, all three sites are distinct. Analysis of the primary structure of the GABA receptor indicates that there are at least three subunits (α , β , γ); benzodiazepine binds to the γ subunit.

The calming effects of benzodiazepines are therefore best explained by an enhancement of certain of the inhibitory effects of GABA. Inverse agonists of benzodiazepine reduce rather than enhance GABA-ergic transmission and produce anxiety as well as predisposition to convulsions. Yet these inverse agonists bind to the benzodiazepine site on the GABA receptor and are blocked by benzodiazepine antagonists.

This has raised the possibility that endogenous inverse agonists might mediate naturally occurring anxiety states. High concentrations of GABA receptors have been found in the limbic system, specifically in the amygdala, an area thought to be of central importance for emotional behavior. However, as with other mental illnesses, it is unlikely that a single transmitter system is responsible for the illness. In fact, many patients with anxiety states respond extremely well to selective serotonin reuptake inhibitors and tricyclic antidepressants.

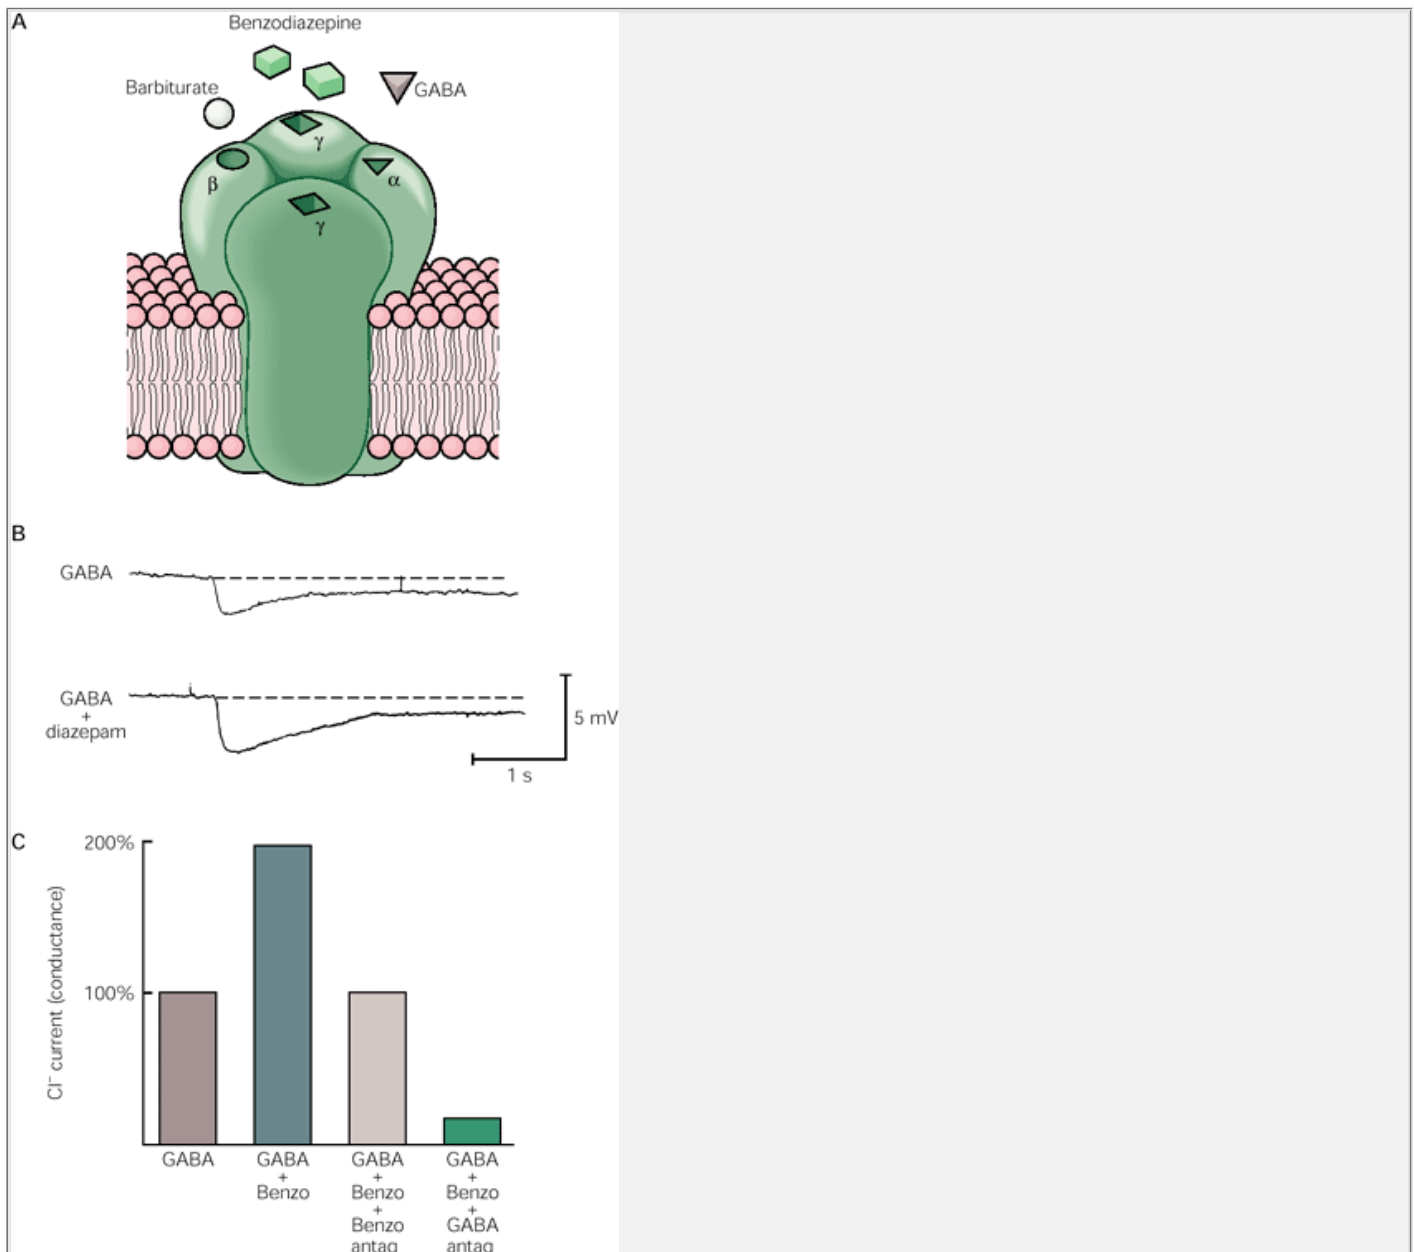

Figure 61-9 Benzodiazepines act on the GABA channel.

A. Structural model of the GABA_A chloride channel. The channel protein contains at least five different subunit types, of which only three are illustrated here (α , β , γ). Benzodiazepines bind to the γ subunits, GABA to the α subunit, and barbiturates to the β subunit. All the subunits contribute to forming the Cl⁻ channel. When GABA binds to GABA_A receptors the Cl⁻ channels open and the influx of Cl⁻ hyperpolarizes the cell.

B. Diazepam, a benzodiazepine, is an effective drug in treating generalized anxiety disorders. The traces compare the responses of a mouse spinal cord neuron to GABA, the major inhibitory neurotransmitter in the brain, and to GABA in the presence of diazepam. Diazepam increases the affinity of the receptor for GABA and thus increases the Cl⁻ conductance and the hyperpolarizing current.

C. Benzodiazepine (Benzo) modulates Cl⁻ flux through the channel by enhancing the effect of GABA, which itself enhances the influx of Cl⁻ into the nerve cell. As a result, basal levels of GABA become more effective in gating the channel. Benzodiazepine antagonists prevent enhancement of GABA effects but do not reduce the basal conductance of Cl⁻. GABA antagonists prevent gating of Cl⁻ channels in spite of the presence of benzodiazepines.

P.1223

In Obsessive-Compulsive Disorder Obsrusive Thoughts Are a Source of Anxiety and Compulsion

Obsessive-compulsive disorders are usually chronic disorders with recurrent obsessions and compulsions as the predominant features. *Obsessions* are persistent and intrusive ideas, thoughts, images, or impulses that commonly fall into one of two categories: doubts or fears. Obsessive doubting can penetrate daily life, leaving patients repeatedly unsure whether the apartment door was locked, whether the stove was turned off, or whether their hands are clean enough. This preoccupation can result in excessive hand washing, sometimes to the extent of soreness or removal of skin. Obsessive fears focus on unrealistic and improbable dangers, such as the prospect of killing someone driving a car or lighting the stove. Interestingly, the person experiencing these fears typically views them as alien—senseless and unwanted invasions of consciousness. When the fears first become prominent, the patient attempts to ignore or suppress them, usually unsuccessfully. Later in the course of the illness the patient may no longer actively resist these fears.

To alleviate the anxiety and diminish the discomfort of the obsessive thoughts or urges, the patient often begins to carry out compulsive acts. In contrast to obsessions, which are repetitive ideas, *compulsions* are repetitive acts. To be defined as a compulsion a behavior must be repeated excessively and the repetition must not be realistically related to any environmental condition. The most common compulsions are handwashing, counting, checking, touching, and pulling out of hair.

The severe symptoms of obsessive-compulsive disorder are thought to represent the extreme end of a behavioral continuum that includes a compulsive lifestyle that typically begins between 18 and 25 years of age. Although the symptoms may disappear or become less severe for periods of time, the disorder rarely disappears.

P.1224

Indeed, people with obsessive-compulsive disorder may also have other mental illness, such as depression, other anxiety disorders (panic attacks, eating disorders), or social phobias.

Figure 61-10 Patients with obsessive-compulsive disorder tend to show hyperactivity in the head of the caudate. This hyperactivity can be reduced in one of two ways: by selective serotonin reuptake inhibitors (**top**), medication therapy, or cognitive therapy (**bottom**), psychotherapy.

Obsessive-compulsive disorder is thought to reflect a disturbance of the basal ganglia. In fact, some forms of obsessive-compulsive disorder seem to be related to Tourette syndrome, a hereditary chronic motor tic disorder that has its locus in the basal ganglia. Patients with Tourette syndrome erupt in repetitive grunts, noises, and even obscenities that are not under the patient's control. Several other neurological syndromes that involve the basal ganglia, such as postencephalitic Parkinson disease, Sydenham chorea, bilateral necrosis of the globus pallidus, and Huntington disease, often are associated with a component of obsessive-compulsive disorder.

The head of the caudate nucleus and the pathway that connects the caudate with the prefrontal (orbitofrontal) cortex and cingulate gyrus seems to be hyperactive in obsessive-compulsive disorder. The caudate nucleus sends GABA-ergic inhibitory projections to the globus pallidus (one of the two major output elements of the striatum), which sends inhibitory projections to the thalamus, which then projects to the orbitofrontal cortex. The presence of serial inhibitory pathways—from the caudate nucleus to the globus pallidus, and from there to the thalamus—suggests the possibility that a disease state produces a disinhibition, which could lead to reverberating activity in this circuit. Perhaps an increase in the first inhibitory pathway causes the second pathway to become less of an inhibitor of its targets, leading to the reverberatory state.

Obsessive-compulsive disorder is responsive to two types of treatments: (1) specific behavioral therapies based on conditioning ([Chapter 62](#)) and (2) specific serotonin reuptake inhibitors. The effectiveness of the serotonin reuptake inhibitors raises two questions: Is central serotonergic transmission abnormal in obsessive-compulsive disorder and, if so, can psychotherapy reverse this effect? In fact, serotonergic innervation of the striatum is extensive. This innervation is localized to the medial-ventral aspects of the head of the caudate nucleus and to the nucleus accumbens, regions that receive input from the orbitofrontal and cingulate cortex regions thought to be involved in emotional behavior. Surgical lesions of these tracts from the frontal cortex to subcortical sites has improved the symptoms of some otherwise intractable cases. After effective treatment of the disease with either serotonin reuptake inhibitors or behavioral therapy, hyperactivity of the caudate nucleus and orbitofrontal cortex decreases significantly ([Figure 61-10](#)). This suggests that psychotherapy and pharmacologic therapy lead to a similar biological change.

An Overall View

Certain major depressive illnesses may be the result of genetically determined defects in chemical synaptic transmission involving at least two major transmitter pathways of the brain: the serotonergic and noradrenergic systems. Although the mechanisms that cause the defects in transmission remain obscure, progress in studying allelic variations in the human genome provide hope that aspects of the molecular basis of affective disorders might soon be elucidated.

Because there are good animal models of anxiety and we now know a great deal about the amygdala and the neural circuitry in learned fear, it is likely that anxiety may soon be better understood. Like major depression and schizophrenia, two types of anxiety—panic disorder and generalized anxiety disorder—seem to reflect alterations in synaptic functioning. Since panic disorder responds well to certain antidepressants, it too may reflect an abnormality in the biogenic amine pathways of the brain. In contrast, generalized anxiety disorder may involve the GABA_A receptor system, or more likely an abnormality in the interaction of the GABA_A receptor and the serotonergic system.

P.1225

Perhaps the most powerful insight into obsessive-compulsive disorders is the finding that psychotherapy and selective serotonin reuptake inhibitors are equally effective in reversing the symptoms and in so doing they also reverse the anatomical abnormalities.

Learning and Memory

Eric R. Kandel

Irving Kupfermann

Susan Iversen

BEHAVIOR IS THE RESULT OF the interaction between genes and the environment. In earlier chapters we saw how genes influence behavior. We now examine how the environment influences behavior. In humans the most important mechanisms by which the environment alters behavior are learning and memory. Learning is the process by which we acquire knowledge about the world, while memory is the process by which that knowledge is encoded, stored, and later retrieved.

Many important behaviors are learned. Indeed, we are who we are largely because of what we learn and what we remember. We learn the motor skills that allow us to master our environment, and we learn languages that enable us to communicate what we have learned, thereby transmitting cultures that can be maintained over generations. But not all learning is beneficial. Learning also produces dysfunctional behaviors, and these behaviors can, in the extreme, constitute psychological disorders. The study of learning therefore is central to understanding behavioral disorders as well as normal behavior, since what is learned can often be unlearned. When psychotherapy is successful in treating behavioral disorders, it often does so by creating an environment in which people can learn to change their patterns of behavior.

As we have emphasized throughout this book, neural science and cognitive psychology have now found a common ground, and we are beginning to benefit from the increased explanatory power that results from the convergence of two initially disparate disciplines. The rewards of the merger between neural science and cognitive psychology are particularly evident in the study of learning and memory.

In the study of learning and memory we are interested in several questions. What are the major forms of

P.1228

learning? What types of information about the environment are learned most easily? Do different types of learning give rise to different memory processes? How is memory stored and retrieved?

In this chapter we review the major biological principles of learning and memory that have emerged from clinical and cognitive/psychological approaches. In the next chapter we shall examine learning and memory processes at the cellular and molecular level.

Memory Can Be Classified as Implicit or Explicit on the Basis of How Information Is Stored and Recalled

As early as 1861 Pierre Paul Broca had discovered that damage to the posterior portion of the left frontal lobe (Broca's area) produces a specific deficit in language ([Chapter 1](#)). Soon thereafter it became clear that other mental functions, such as perception and voluntary movement, can be related to the operation of discrete neural circuits in the brain. The successes of efforts to localize brain functions led to the question: Are there also discrete systems in the brain concerned with memory? If so, are all memory processes located in one region, or are they distributed throughout the brain?

In contrast to the prevalent view about the localized operation of other cognitive functions, many students of learning doubted that memory functions could be localized. In fact, until the middle of the twentieth century many psychologists doubted that memory was a discrete function, independent of perception, language, or movement. One reason for the persistent doubt is that memory storage does indeed involve many different regions of the brain. We now appreciate, however, that these regions are not equally important. There are several fundamentally different types of memory storage, and certain regions of the brain are much more important for some types of storage than for others.

The first person to obtain evidence that memory processes might be localized to specific regions of the human brain was the neurosurgeon Wilder Penfield. Penfield was a student of Charles Sherrington, the pioneering English neurophysiologist who, at the turn of the century, mapped the motor representation of anesthetized monkeys by systematically probing the cerebral cortex with electrodes and recording the activity of motor nerves. By the 1940s Penfield had begun to apply similar methods of electrical stimulation to map the motor, sensory, and language functions in the cerebral cortex of patients undergoing brain surgery for the relief of focal epilepsy. Since the brain itself does not have pain receptors, brain surgery is painless and can be carried out under local anesthesia in patients that are fully awake. Thus, patients undergoing brain surgery are able to describe what they experience in response to electrical stimuli applied to different cortical areas. On hearing about these experiments, Sherrington, who had always worked with monkeys and cats, told Penfield, "It must be great fun to put a question to the [experimental] preparation and have it answered!"

Penfield explored the cortical surface in more than a thousand patients. On rare occasions he found that electrical stimulation of the temporal lobes produced what he called an *experiential response* — a coherent recollection of an earlier experience. These studies were provocative, but they did not convince the scientific community that the temporal lobe is critical for memory because all of the patients Penfield studied had epileptic seizure foci in the temporal lobe, and the sites most effective in eliciting experiential responses were near those foci. Thus the responses might have been the result of localized seizure activity. Furthermore, the responses occurred in only 8% of all attempts at stimulating the temporal lobes. More convincing evidence that the temporal lobes are important in memory emerged in the mid 1950s from the study of patients who had undergone bilateral removal of the hippocampus and neighboring regions in the temporal lobe as treatment for epilepsy.

The first and best-studied case of the effects on memory of bilateral removal of portions of the temporal lobes was the patient called H.M., studied by Brenda Milner, a colleague of Penfield and the surgeon William Scoville. H.M., a 27-year-old man, had suffered for over 10 years from untreatable bilateral temporal lobe seizures as a consequence of brain damage sustained at age 9 when he was hit and knocked over by someone riding a bicycle. As an adult he was unable to work or lead a normal life. At surgery the hippocampal formation, the amygdala, and parts of the multimodal association area of the temporal cortex were removed bilaterally ([Figure 62-1](#)).

H.M.'s seizures were much better controlled after surgery, but the removal of the medial temporal lobes left him with a devastating memory deficit. This memory deficit (or *amnesia*) was quite specific. H.M. still had normal short-term memory, over seconds or minutes. Moreover, he had a perfectly good long-term memory for events that had occurred before the operation. He remembered his name and the job he held, and he vividly remembered childhood events, although he showed some evidence of a retrograde amnesia for information acquired in the years just before surgery. He retained a perfectly good command of language, including his normally varied vocabulary, and his IQ remained unchanged in the range of bright-normal.

Figure 62-1 The medial temporal lobe and memory storage.

A. The longitudinal extent of the temporal lobe lesion in the patient known as H.M. in a ventral view of the brain.

B. Cross sections showing the estimated extent of surgical removal of areas of the brain in the patient H.M. Surgery was a bilateral, single-stage procedure. The right side is shown here intact to illustrate the structures that were removed. (Modified from [Milner 1966](#).)

C. Magnetic resonance image (MRI) scan of a parasagittal section from the left side of H.M.'s brain. The calibration bar on the right side of the panel has 1 cm increments. The resected portion of the anterior temporal lobes is indicated with an **asterisk**. The remaining portion of the intraventricular portion of the hippocampal formation is indicated with an **open arrow**. Approximately 2 cm of preserved hippocampal formation is visible bilaterally. Note also the substantial cerebellar degeneration obvious as enlarged folial spaces. (From [Corkin et al. 1997](#).)

P.1229

What H.M. now lacked, and lacked dramatically, was the ability to transfer new short-term memory into long-term memory. He was unable to retain for more than a minute information about people, places, or objects. Asked to remember a number such as 8414317, H.M. could repeat it immediately for many minutes, because of his good short-term memory. But when distracted, even briefly, he forgot the number. Thus, H.M. could not recognize people he met after surgery, even when he met them again and again. For example, for several years he saw Milner on an almost monthly basis, yet each time she entered the room H.M. reacted as though he had never seen her before. H.M. had a similarly profound difficulty with spatial orientation. It took him about a year to learn his way around a new house. H.M. is not unique. All patients with extensive bilateral lesions of the limbic association areas of the medial temporal lobe, from either surgery or disease, show similar memory deficits.

The Distinction Between Explicit and Implicit Memory Was First Revealed With Lesions of the Limbic Association Areas of the Temporal Lobe

Milner originally thought that the memory deficit after bilateral medial temporal lobe lesions affects all forms of memory equally. But this proved not to be so. Even though patients with lesions of the medial temporal lobe have profound memory deficits, they are able to learn certain types of tasks and retain this learning for as long as normal subjects. The spared component of

P.1230

memory was first revealed when Milner discovered that H.M. could learn new motor skills at a normal rate. For example, he learned to draw the outlines of a star while looking at his hand and the star in a mirror ([Figure 62-2](#)). Like normal subjects learning this task, H.M. initially made many mistakes, but after several days of training his performance was error-free and indistinguishable from that of normal subjects.

Figure 62-2 The patient H.M. showed definite improvement in any task involving learning skilled movements. He was taught to trace between two outlines of a star while viewing his hand in a mirror. He improved considerably with each fresh test, although he had no recollection that he had ever done the task before. The graph plots the number of times, in each trial, that he strayed outside the outlines as he drew the star. (From [Blakemore 1977.](#))

Later work by Larry Squire and others has made it clear that the memory capacities of H.M. and other patients with bilateral medial temporal lobe lesions are not limited to motor skills. Rather, these patients are capable of various forms of simple reflexive learning, including habituation, sensitization, classical conditioning, and operant conditioning, which we discuss later in this chapter. Furthermore, they are able to improve their performance on certain perceptual tasks. For example, they do well with a form of memory called *priming*, in which the recall of words or objects is improved by prior exposure to the words or object. Thus, when shown the first few letters of previously studied words, a subject with amnesia correctly selects as many previously presented words as do normal subjects, even though the subject has *no* conscious memory of having seen the word before ([Figure 62-3](#))

The memory capability that is spared in patients with bilateral lesions of the temporal lobe typically involves learned tasks that have two things in common. First, the tasks tend to be reflexive rather than reflective in nature and involve habits and motor or perceptual skills. Second, they do not require conscious awareness or complex cognitive processes, such as comparison and evaluation. The patient need only respond to a stimulus or cue, and need not try to remember anything. Thus, when given a highly complex mechanical puzzle to solve the patient may learn it as quickly and as well as a normal person, but will not consciously remember having worked on it previously. When asked why the performance of a task is much better after several days of practice than on the first day, the patient may respond, "What are you talking about? I've never done this task before."

Although these two fundamentally different forms of memory—for skills and for knowledge—have been demonstrated in detail in amnesia patients with lesions of the temporal lobe, they are not unique amnesiacs. Cognitive psychologists had previously distinguished these two types of memory in normal subjects. They refer to information about how to perform something as *implicit memory* (also referred to as *nondeclarative memory*), a memory that is recalled unconsciously. Implicit memory is typically involved in training reflexive motor or perceptual skills. Factual knowledge of people, places, and things, and what these facts mean, is referred to as *explicit memory* (or *declarative memory*). This is recalled by a deliberate, conscious effort ([Figure 62-4](#)). Explicit memory is highly flexible and involves the association of multiple bits and pieces of information. In contrast, implicit memory is more rigid and tightly connected to the original stimulus conditions under which the learning occurred

The psychologist Endel Tulving first developed the idea that explicit memory can be further classified as *episodic* (a memory for events and personal experience) or *semantic* (a memory for facts). We use episodic memory when we recall that we saw the first flowers of spring yesterday or that we heard Beethoven's *Moonlight Sonata*

P.1231

several months ago. We use semantic memory to store and recall objective knowledge, the kind of knowledge we learn in school and from books. Nevertheless, all explicit memories can be concisely expressed in declarative statements, such as "Last summer I visited my grandmother at her country house" (episodic knowledge) or "Lead is heavier than water" (semantic knowledge).

Figure 62-3 In a study of recall of words, amnesiacs and normal control subjects were tested under two conditions. First they were presented with common words and then asked to recall the words (free recall). Amnesiac patients were impaired in this condition. However, when subjects were given the first three letters of a word and instructed simply to form the first word that came to mind (completion), the amnesiacs performed as well as normal subjects. The baseline guessing rate in the word completion condition was 9%. (From [Squire 1987](#).)

Figure 62-4 Various forms of memory can be classified as either explicit (declarative) or implicit (nondeclarative).

Animal Studies Help to Understand Memory

The surgical lesion of H.M.'s temporal lobe encompassed a number of regions, including the temporal pole, the ventral and medial temporal cortex, the amygdala, and the hippocampal formation (which includes the hippocampus proper, the subiculum, and the dentate gyrus) as well as the surrounding entorhinal, perirhinal, and parahippocampal cortices. Since lesions restricted to any one of these several sectors of the medial temporal lobe are rare in humans, experimental lesion studies in monkeys have helped define the contribution of the different parts of the temporal lobe to memory formation.

Mortimer Mishkin and Squire produced lesions in monkeys identical to those reported for H.M. and found defects in explicit memory for places and objects similar to those observed in H.M. Damage to the amygdala alone had no effect on explicit memory. Although the amygdala stores components of memory concerned with emotion ([Chapter 50](#)), it does not store factual information. In contrast, selective damage to the hippocampus or the polymodal association areas in the temporal cortex with which the hippocampus connects—the perirhinal and parahippocampal cortices—produces clear impairment of explicit memory.

Thus, studies with human patients and with experimental animals suggest that knowledge stored as explicit memory is first acquired through processing in one or more of the three polymodal association cortices (the prefrontal, limbic, and parieto-occipital-temporal cortices) that synthesize visual, auditory, and somatic information. From there the information is conveyed in series to the parahippocampal and perirhinal cortices,

P.1232

then the entorhinal cortex, the dentate gyrus, the hippocampus, the subiculum, and finally back to the entorhinal cortex. From the entorhinal cortex the information is sent back to the parahippocampal and perirhinal cortices and finally back to the polymodal association areas of the neocortex ([Figure 62-5](#)).

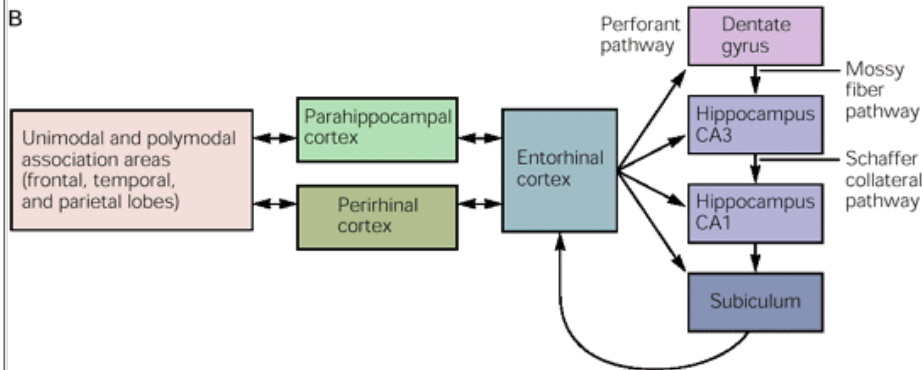

Figure 62-5 The anatomical organization of the hippocampal formation.

A. The key components of the medial temporal lobe important for memory storage can be seen in the medial (**left**) and ventral (**right**) surface of the cerebral hemisphere.

B. The input and output pathways of the hippocampal formation.

Thus, in processing information for explicit memory storage the entorhinal cortex has dual functions. First, it is the main input to the hippocampus. The entorhinal cortex projects to the dentate gyrus via the perforant pathway and by this means provides the critical input pathway through which the polymodal information from the association cortices reaches the hippocampus (Figure 62-5B). Second, the entorhinal cortex is also the major output of the hippocampus. The information coming to the hippocampus from the polymodal association cortices and that coming from the hippocampus to the association cortices converge in the entorhinal cortex. It is therefore understandable why the memory impairments associated with damage to the entorhinal cortex are particularly severe and why this damage affects not simply one but all sensory modalities. In fact, the earliest pathological changes in Alzheimer disease, the major degenerative disease that affects explicit memory storage, occurs in the entorhinal cortex.

P.1233

Damage Restricted to Specific Subregions of the Hippocampus Is Sufficient to Impair Explicit Memory Storage

Given the large size of the hippocampus proper, how extensive does a bilateral lesion have to be to interfere with explicit memory storage? Clinical evidence from several patients, as well as studies in experimental animals, suggests that a lesion restricted to *any* of the major components of the system can have a significant effect on memory storage. For example Squire, David Amaral, and their colleagues found that the patient R.B. had only one detectable lesion after a cardiac arrest—a destruction of the pyramidal cells in the CA1 region of the hippocampus. Nevertheless, R.B. had a defect in explicit memory that was qualitatively similar to that of H.M., although quantitatively it was much milder.

The different regions of the medial temporal lobe may, however, not have equivalent roles. Although the hippocampus is important for object recognition, for example, other areas in the medial temporal lobe may be even more important. Damage to the perirhinal, parahippocampal, and entorhinal cortices that spares the underlying hippocampus produces a greater deficit in memory storage, such as object recognition than do selective lesions of the hippocampus that spare the overlying cortex.

On the other hand, the hippocampus may be relatively more important for spatial representation. In mice and rats lesions of the hippocampus interfere with memory for space and context, and single cells in the hippocampus encode specific spatial information (Chapter 63). Moreover, functional imaging of the brain of normal human subjects shows that spatial memories involve more intense hippocampal activity in the right hemisphere than do memories for words, objects, or people, while the latter involve greater activity in the hippocampus in the dominant left hemisphere. These physiological findings are consistent with the finding that lesions of the right hippocampus give rise to problems with spatial orientation, whereas lesions of the left hippocampus give rise to defects in verbal memory (Figure 62-6).

Explicit Memory Is Stored in Association Cortices

Lesions of the medial temporal lobe in patients such as H.M. and R.B. interfere only with the long-term storage of *new* memories. These patients retain a reasonably good memory of earlier events, although with severe lesions such as those of H.M. there appears to be some retrograde amnesia for the years just before the operation. How does this come about?

The fact that patients with amnesia are able to remember their childhood, the lives they have led, and the factual knowledge they acquired before damage to the hippocampus suggests that the hippocampus is only a temporary way station for long-term memory. If so, long-term storage of episodic and semantic knowledge would occur in the unimodal or multimodal association areas of the cerebral cortex that initially process the sensory information.

For example, when you look at someone's face, the sensory information is processed in a series of areas of the cerebral cortex devoted to visual information, including the unimodal visual association area in the inferotemporal cortex specifically concerned with face recognition (see Box 28-1 and Chapter 28). At the same time, this visual information is also conveyed through the mesotemporal association cortex to the parahippocampal, perirhinal, and entorhinal cortices, and from there through the perforant pathway to the hippocampus. The hippocampus and the rest of the medial temporal lobe may then act, over a period of days or weeks, to facilitate storage of the information about the face initially processed by the visual association area of the inferotemporal lobe. The cells in the visual association cortex concerned with faces are interconnected with other regions that are thought to store additional knowledge about the person whose face is seen, and these connections could also be modulated by the hippocampus. Thus the hippocampus might also serve to bind together the various components of a richly processed memory of a person.

Viewed in this way the hippocampal system would mediate the initial steps of long-term storage. It would then slowly transfer information into the neocortical storage system. The relatively slow addition of information to the neocortex would permit new data to be stored in a way that does not disrupt existing information. If the association areas are the ultimate repositories for explicit memory, then damage to association cortex should destroy or impair recall of explicit knowledge that is acquired before the damage. This is in fact what happens. Patients with lesions in association areas have difficulty in recognizing faces, objects, and places in their familiar world. Indeed, lesions in different association areas give rise to specific defects in either semantic or episodic memory.

Semantic (Factual) Knowledge Is Stored in a Distributed Fashion in the Neocortex

As we have seen, semantic memory is that type of long-term memory that embraces knowledge of objects, facts, and concepts as well as words and their

meaning. It includes the naming of objects, the definitions of spoken words, and verbal fluency.

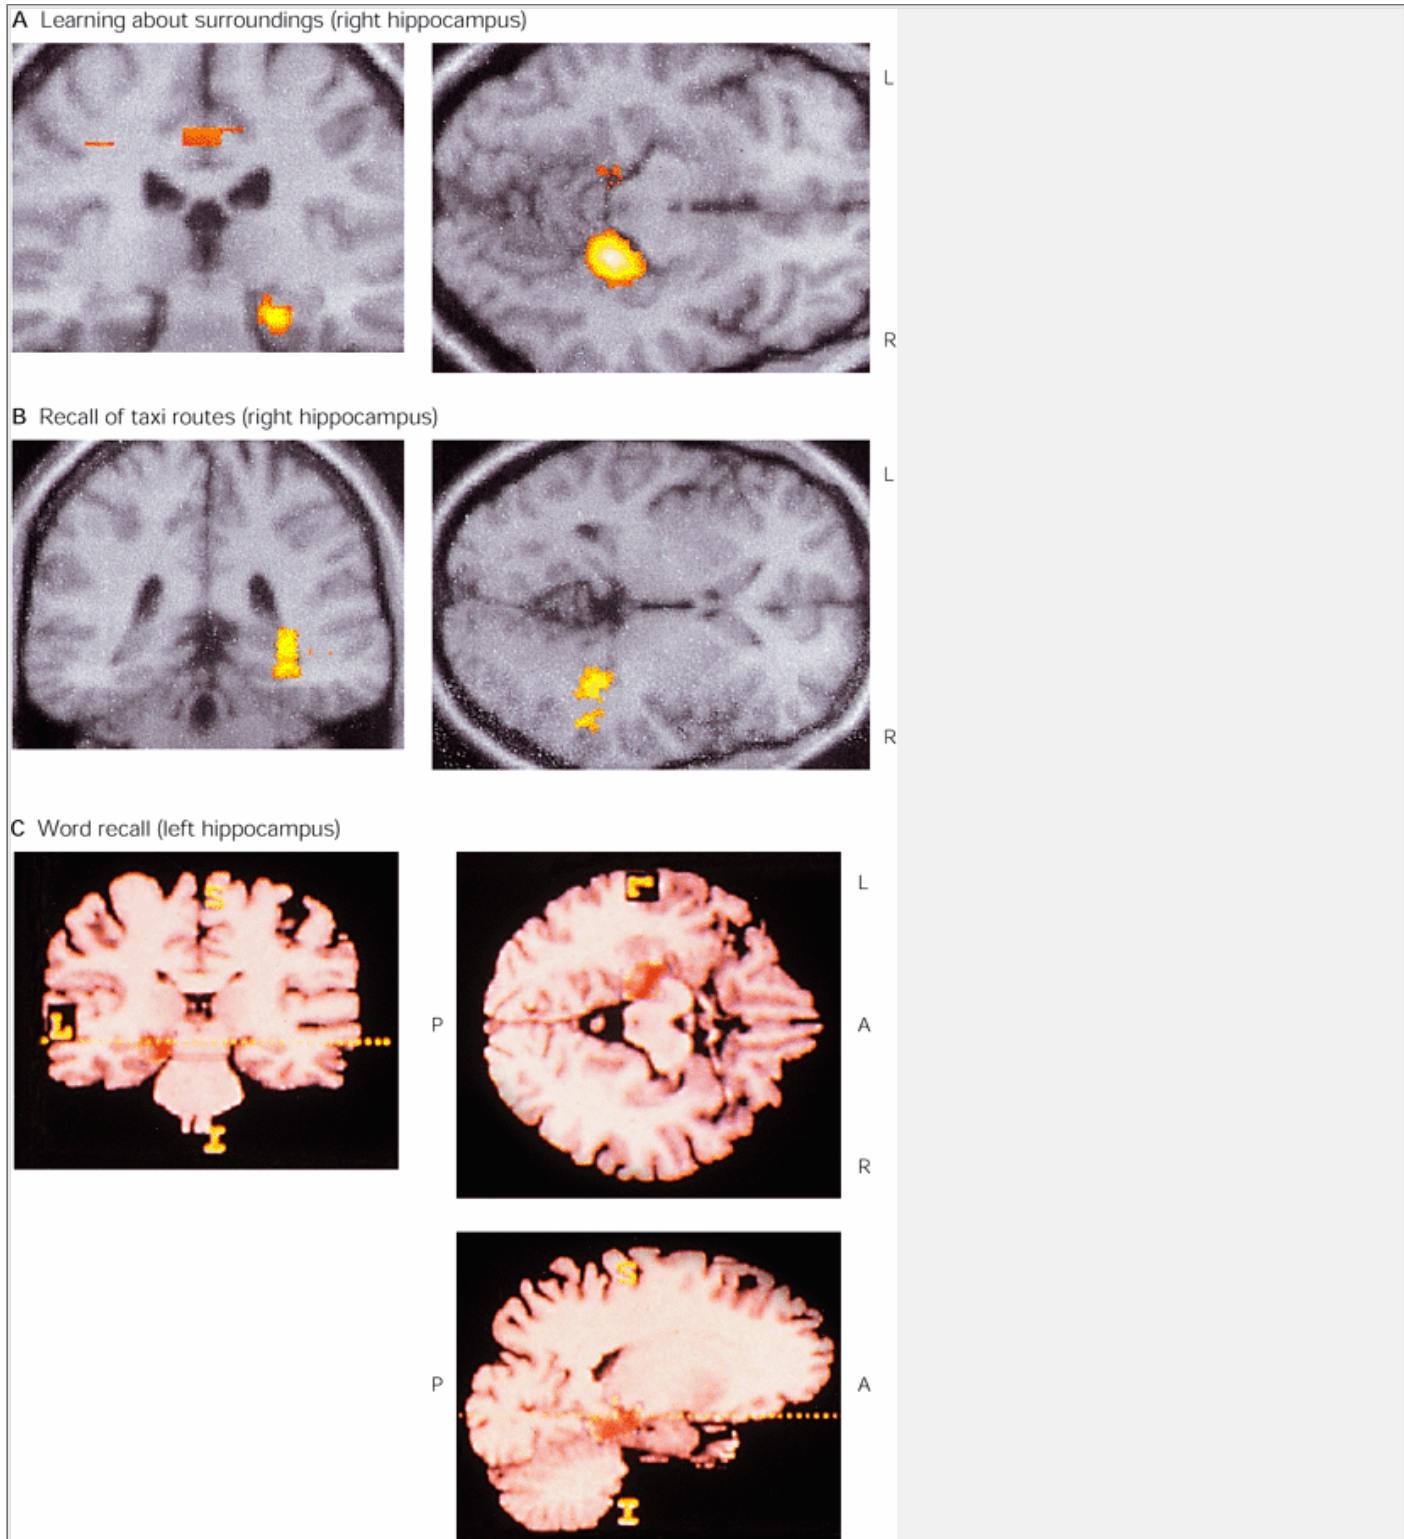

Figure 62-6 The role of the hippocampus in memory. We spend much of our time actively moving around our environment. This requires that we have a representation in our brain of the external environment, a representation that can be used to find our way around. The right hippocampus seems to be importantly involved in this representation, whereas the left hippocampus is concerned with verbal memory.

A. The right hippocampus is activated during learning about the environment. These scans were made while subjects watched a film that depicted navigation through the streets of an Irish town. The activity during this task was compared with that in the control task where the camera was static and people and cars came by it. In the latter case there was no learning of spatial relationships and the hippocampus was not activated. Areas with significant changes in activity, indexed by local perfusion change, are indicated in **yellow** and **orange**. The scan on the left is a coronal section and the scan on the right is a transaxial section; in each panel the front of the brain is on the right and the occipital lobe on the left. (From [Maguire et al. 1996](#).)

B. The right hippocampus also is activated during the recall by licensed taxi drivers of routes around the city of London. These people spend a long time learning the intricacies of the road network in the city and are able to describe the shortest routes between landmarks as well as the names of the various streets. The right parahippocampal and hippocampal regions are significantly activated when they do this task. The scan on the left is a coronal section and the scan on the right is a transaxial section; in each panel the front of the brain is on the right and the occipital lobe on the left. Areas with significant changes in activity, indexed by local perfusion change, are depicted in **yellow** and **orange**. (From [Maguire et al. 1996](#).)

C. Three anatomical slices in the coronal (**left upper**), transverse (**right upper**), and sagittal (**right lower**) planes show activation (**red**) in the left hippocampus associated with the successful retrieval of words from long lists that have to be memorized. **A** = anterior, **P** = posterior, **I** = inferior.

How is semantic knowledge built up? How is it stored in the cortex? The organization and flexibility of semantic knowledge is both remarkable and surprising. Consider a complex visual image such as a photograph of an elephant. Through experience this visual image becomes associated with other forms of knowledge about elephants, so that eventually when we close our eyes and conjure up the image of an elephant, the image is based on a rich representation of the concept of an elephant. The more associations we have made to the

P.1235

image of the elephant, the better we *encode* that image, and the better we can recall the features of an elephant at a future time. Furthermore, these associations fall into different categories. For example, we commonly know that an elephant is a living rather than a nonliving thing, that it is an animal rather than a plant, that it lives in a particular environment, and that it has unique physical features and behavior patterns and emits a distinctive set of sounds. Moreover, we know that elephants are used by humans to perform certain tasks and that they have a specific name. The word *elephant* is associated with all of these pieces of information, and any one bit of information can open access to all of our knowledge about elephants.

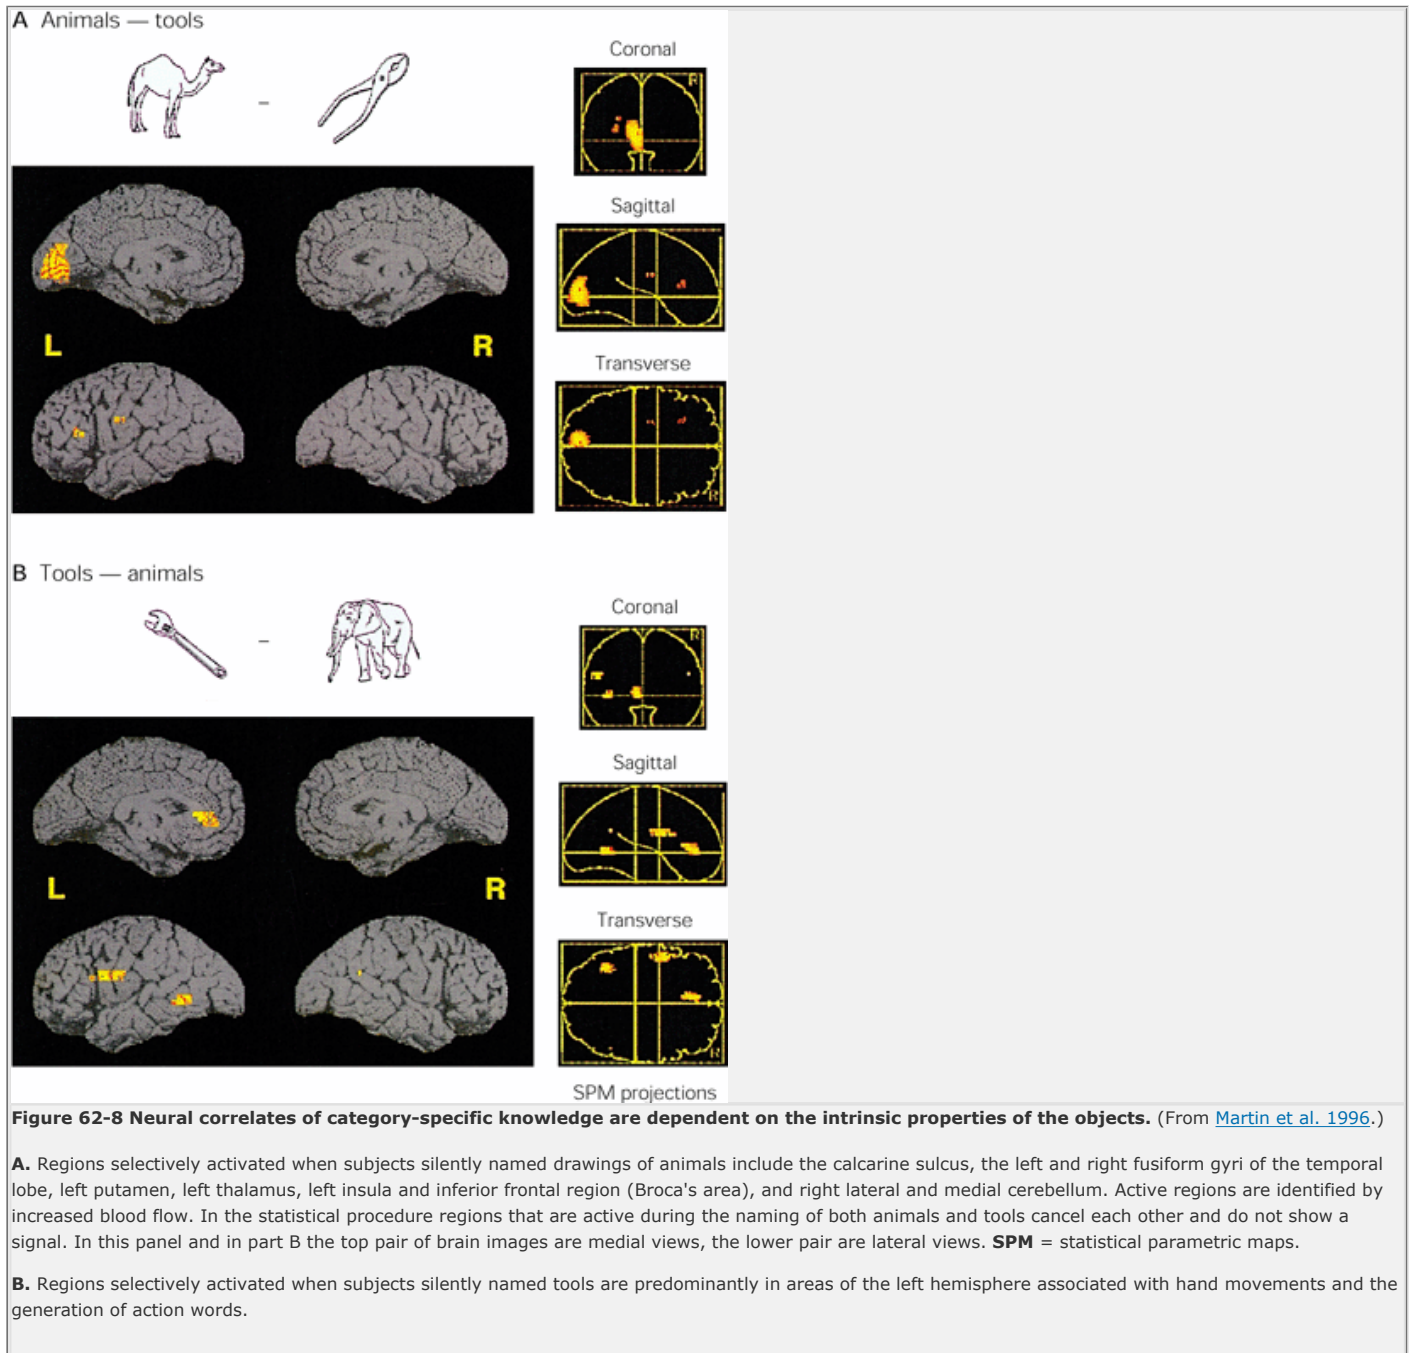

As this example illustrates, we build up semantic knowledge through associations over time. The ability

P.1236

to recall and use knowledge—our *cognitive efficiency*—is thought to depend on how well these associations have organized the information we retain. As we first saw in [Chapter 1](#), when we recall a concept it comes to mind in one smooth and continuous operation. However, studies of patients with damage to the association cortices have shown that different representations of an object—say, different aspects of elephants—are stored separately. These studies have made clear that our experience of knowledge as a seamless, orderly, and cross-referenced database is the product of integration of multiple representations in the brain at many distinct anatomical sites, each concerned with only one aspect of the concept that came to mind. Thus, there is no general semantic memory store; semantic knowledge is not stored in a single region. Rather, each time knowledge about anything is recalled, the recall is built up from distinct bits of

information, each of which is stored in specialized (*dedicated*) memory stores. As a result, damage to a specific cortical area can lead to loss of specific information and therefore a fragmentation of knowledge.

For example, damage to the posterior parietal cortex can result in *associative visual agnosia*; patients cannot *name* objects but they can *identify* objects by selecting the correct drawing and can faithfully reproduce detailed drawings of the object ([Figure 62-7](#)). In contrast, damage to the occipital lobes and surrounding region can result in an *apperceptive visual agnosia*; patients are unable to draw objects but they can name them if appropriate perceptual cues are available ([Figure 62-7](#)).

While verbal and visual knowledge about objects involve different circuitry, visual knowledge involves even further specialization. For example, visual knowledge about faces and about inanimate objects is represented in different cortical areas. As we have seen in [Chapter 25](#), lesions in the inferotemporal cortex can result in

P.1237

prosopagnosia, the inability to recognize familiar faces or learn new faces, but these lesions can leave intact all other aspects of visual recognition. Conversely, positron emission tomography (PET) imaging studies show that object recognition activates the left occipitotemporal cortex and not the areas in the right hemisphere associated with face recognition. Thus, not all of our visual knowledge is represented in the same locus in the occipitotemporal cortex.

Category-specific defects in object recognition were first described by Rosaleen McCarthy and Elizabeth Warrington. They found that certain lesions interfere with the memory (knowledge) of living objects but not with memory of inanimate, manufactured objects. For example, one patient's verbal knowledge of living things was greatly impaired. When asked to define "rhinoceros" the patient responded by merely saying "animal." But when shown a picture of a rhinoceros he responded, "enormous, weighs over a ton, lives in Africa." The same patient's semantic knowledge of inanimate things was readily accessible through both verbal and visual cues. For example, when asked to define "wheelbarrow" he replied, "The thing we have here in the garden for carrying bits and pieces; wheelbarrows are used by people doing maintenance here on your buildings. They can put their cement and all sorts of things in it to carry it around."

To investigate further the neural correlates of category-specific knowledge for animate and inanimate objects, Leslie Ungerleider and her colleagues used PET scanning to map regions of the normal brain that are associated with naming animals and regions that are involved in naming of tools. They found that naming of animals and tools both involved bilateral activation of the ventral temporal lobes and Broca's area. In addition the naming animals selectively activated the left medial temporal lobe, a region involved in the earlier stages of visual processing. In contrast, the naming tools selectively activated a left premotor area, an area also activated with hand movements, as well as an area in the left middle temporal gyrus that is activated when action words are spoken. Thus, the brain regions active during object identification are dependent in part on the intrinsic properties of the objects presented ([Figure 62-8](#)).

Episodic (Autobiographical) Knowledge About Time and Place Seems to Involve the Prefrontal Cortex

Whereas some lesions to multimodal association areas interfere with semantic knowledge, others interfere with the capacity to recall any episodic event experienced more than a few minutes previously, including dramatic personal events such as accidents and deaths in the family that occurred before the trauma. Remarkably, patients with loss of episodic memory still have the ability to recall vast stores of factual (semantic) knowledge. One patient could remember all personal facts about his friends and famous people, such as their names and their characteristics, but could not remember any specific events involving these individuals.

The areas of the neocortex that seem to be specialized for long-term storage of episodic knowledge are the association areas of the frontal lobes. These prefrontal areas work with other areas of the neocortex to allow recollection of when and where a past event occurred (Chapter 19). A particularly striking symptom in patients with frontal lobe damage is their tendency to forget how information was acquired, a deficit called *source amnesia*. Since the ability to associate a piece of information with the time and place it was acquired is at the core of how accurately we remember the individual episodes of our lives, a deficit in source information interferes dramatically with the accuracy of recall of episodic knowledge.

Explicit Knowledge Involves at Least Four Distinct Processes

We have learned three important things about episodic and semantic knowledge. First, there is not a single, all-purpose memory store. Second, any item of knowledge has multiple representations in the brain, each of which corresponds to a different meaning and can be accessed independently (by visual, verbal, or other sensory clues). Third, both semantic and episodic knowledge are the result of at least four related but distinct types of processing: encoding, consolidation, storage, and retrieval (Figure 62-9).

Encoding refers to the processes by which newly learned information is attended to and processed when first encountered. The extent and nature of this encoding are critically important for determining how well the learned material will be remembered at later times. For a memory to persist and be well remembered, the incoming information must be encoded thoroughly and deeply. This is accomplished by attending to the information and associating it meaningfully and systematically with knowledge that is already well established in memory so as to allow one to integrate the new information with what one already knows. Memory storage is stronger when one is well motivated.

Consolidation refers to those processes that alter the newly stored and still labile information so as to make it more stable for long-term storage. As we shall learn in the next chapter, consolidation involves the expression of genes and the synthesis of new proteins, giving rise to

P.1238

structural changes that store memory stably over time.

Storage refers to the mechanism and sites by which memory is retained over time. One of the remarkable features about long-term storage is that it seems to have an almost unlimited capacity. In contrast, short-term working memory is very limited.

Finally, *retrieval* refers to those processes that permit the recall and use of the stored information. Retrieval involves bringing different kinds of information together that are stored separately in different storage sites. Retrieval of memory is much like perception; it is a constructive process and therefore subject to distortion, much as perception is subject to illusions ([Box 62-1](#)).

Retrieval of information is most effective when it occurs in the same context in which the information was acquired and in the presence of the same cues (retrieval cues) that were available to the subject during learning. Retrieval, particularly of explicit memories, is critically dependent on short-term working memory, a form of memory to which we now turn.

Working Memory Is a Short-Term Memory Required for Both the Encoding and Recall of Explicit Knowledge

How is explicit memory recalled and brought to consciousness? How do we put it to work? Both the initial encoding and the ultimate recall of explicit knowledge (and perhaps some forms of implicit knowledge as well) are thought to require recruitment of stored information

P.1239

into a special short-term memory store called *working memory*. As we learned in [Chapter 19](#), working memory is thought to have three component systems.

Box 62-1 The Transformation of Explicit Memories

How accurate is explicit memory? This question was explored by the psychologist Frederic Bartlett in one series of studies in which the subjects were asked to read stories and then retell them. The recalled stories were shorter and more coherent than the original stories, reflecting reconstruction and condensation of the original. The subjects were unaware that they were editing the original stories and often felt more certain about the edited parts than about the unedited parts of the retold story. The subjects were not confabulating; they were merely interpreting the original material so that it made sense on recall.

Observations such as these lead us to believe that explicit memory, at least episodic (autobiographical) memory, is a constructive process like sensory perception. The information stored as explicit memory is the product of processing by our perceptual apparatus. As we saw in earlier chapters, sensory perception itself is not a faithful record of the external world but a constructive process in which incoming information is put together according to rules inherent in the brain's afferent pathways. It is also constructive in the sense that individuals interpret the external environment from the standpoint of a specific point in space as well as from the standpoint of a specific point in their own history. As discussed in [Chapter 25](#), optical illusions nicely illustrate the difference between perception and the world as it is.

Moreover, once information is stored, later recall is not an exact copy of the information originally stored. Past experiences are used in the present as clues that help the brain reconstruct a past event. During recall we use a variety of cognitive strategies, including comparison, inferences, shrewd guesses, and suppositions, to generate a consistent and coherent memory.

An attentional control system (or *central executive*), thought to be located in the prefrontal cortex ([Chapter 19](#)), actively focuses perception on specific events in the environment. The attentional control system has a very limited capacity (less than a dozen items).

The attentional control system regulates the information flow to two rehearsal systems that are thought to maintain memory for temporary use: the articulatory loop for language and the visuospatial sketch pad for vision and action. The *articulatory loop* is a storage system with a rapidly decaying memory trace where memory for words and numbers can be maintained by subvocal speech. It is this system that allows one to hold in mind, through repetition, a new telephone number as one prepares to dial it. The *visuospatial sketch pad* represents both the visual properties and the spatial location of objects to be remembered. This system allows one to store the image of the face of a person one meets at a cocktail party.

The information processed in either one of these rehearsal, working memory systems has the possibility of entering long-term memory. The two rehearsal systems are thought to be located in different parts of the posterior association cortices. Thus, lesions of the extrastriate cortex impair rehearsal of visual imagery whereas lesions in the parietal cortex impair rehearsal of spatial imagery.

Implicit Memory Is Stored in Perceptual, Motor, and Emotional Circuits

Unlike explicit memory, implicit memory does not depend directly on conscious processes nor does recall require a conscious search of memory. This type of memory builds up slowly, through repetition over many trials, and is expressed primarily in performance, not in words. Examples of implicit memory include perceptual and motor skills and the learning of certain types of procedures and rules.

Different forms of implicit memory are acquired through different forms of learning and involve different brain regions. For example, memory acquired through fear conditioning, which has an emotional component, is thought to involve the amygdala. Memory acquired through operant conditioning requires the striatum and cerebellum. Memory acquired through classical conditioning, sensitization, and habituation—three simple forms of learning we shall consider later—involves changes in the sensory and motor systems involved in the learning.

P.1240

Implicit memory can be studied in a variety of perceptual or reflex systems in either vertebrates or invertebrates. Indeed, simple invertebrates provide useful models for studying the neural mechanisms of implicit learning.

Implicit Memory Can Be Nonassociative or Associative

Psychologists often study implicit forms of memory by exposing animals to controlled sensory experiences. Two major procedures (or paradigms) have emerged from such studies, and these have identified two major subclasses of implicit memory: nonassociative and associative. In nonassociative learning the subject learns about the properties of a single stimulus. In associative learning the subject learns about the relationship between two stimuli or between a stimulus and a behavior.

Nonassociative learning results when an animal or a person is exposed once or repeatedly to a single type of stimulus. Two forms of nonassociative learning are common in everyday life: habituation and sensitization. *Habituation* is a decrease in response to a benign stimulus when that stimulus is presented repeatedly. For example, most people are startled when they first hear the sound of a firecracker on the Fourth of July, Independence Day in the United States, but as the celebration progresses they gradually become accustomed to the noise. *Sensitization* (or *pseudoconditioning*) is an enhanced response to a wide variety of stimuli after the presentation of an intense or noxious stimulus. For example, an animal responds more vigorously to a mild tactile stimulus after it has received a painful pinch. Moreover, a sensitizing stimulus can override the effects of habituation, a process called *dishabituation*. For example, after the startle response to a noise has been reduced by habituation, one can restore the intensity of response to the noise by delivering a strong pinch.

Sensitization and dishabituation are not dependent on the relative timing of the intense and the weak stimulus; no association between the two stimuli is needed. Not all forms of nonassociative learning are as simple as habituation or sensitization. For example, imitation learning, a key factor in the acquisition of language, has no obvious associational element.

Two forms of associative learning have also been distinguished based on the experimental procedures used to establish the learning. Classical conditioning involves learning a relationship between two stimuli, whereas operant conditioning involves learning a relationship between the organism's behavior and the consequences of that behavior.

Classical Conditioning Involves Associating Two Stimuli

Since Aristotle, Western philosophers have traditionally thought that learning is achieved through the association of ideas. This concept was systematically developed by John Locke and the British empiricist school of philosophy, important forerunners of modern psychology. Classical conditioning was introduced into the study of learning at the turn of the century by the Russian physiologist Ivan Pavlov. Pavlov recognized that learning frequently consists of becoming responsive to a stimulus that originally was ineffective. By changing the appearance, timing, or number of stimuli in a tightly controlled stimulus environment and observing the changes in selected simple reflexes, Pavlov established a procedure from which reasonable inferences could be made about the relationship between changes in behavior (learning) and the environment (stimuli). According to Pavlov, what animals and humans learn when they associate *ideas* can be examined in its most elementary form by studying the association of *stimuli*.

The essence of classical conditioning is the pairing of two stimuli. The *conditioned stimulus* (CS), such as a light, tone, or tactile stimulus, is chosen because it produces either no overt response or a weak response usually unrelated to the response that eventually will be learned. The reinforcement, or *unconditioned stimulus* (US), such as food or a shock to the leg, is chosen because it normally produces a strong, consistent, overt response (the *unconditioned response*), such as salivation or withdrawal of the leg. Unconditioned responses are innate; they are produced without learning. When a CS is followed by a US, the CS will begin to elicit a new or different response called the *conditioned response*. If the US is rewarding (food or water), the conditioning is termed *appetitive*; if the US is noxious (an electrical shock), the conditioning is termed *defensive*.

One way of interpreting conditioning is that repeated pairing of the CS and US causes the CS to become an anticipatory signal for the US. With sufficient experience an animal will respond to the CS as if it were anticipating the US. For example, if a light is followed repeatedly by the presentation of meat, eventually the sight of the light itself will make the animal salivate. Thus, classical conditioning is a means by which an animal learns to predict events in the environment.

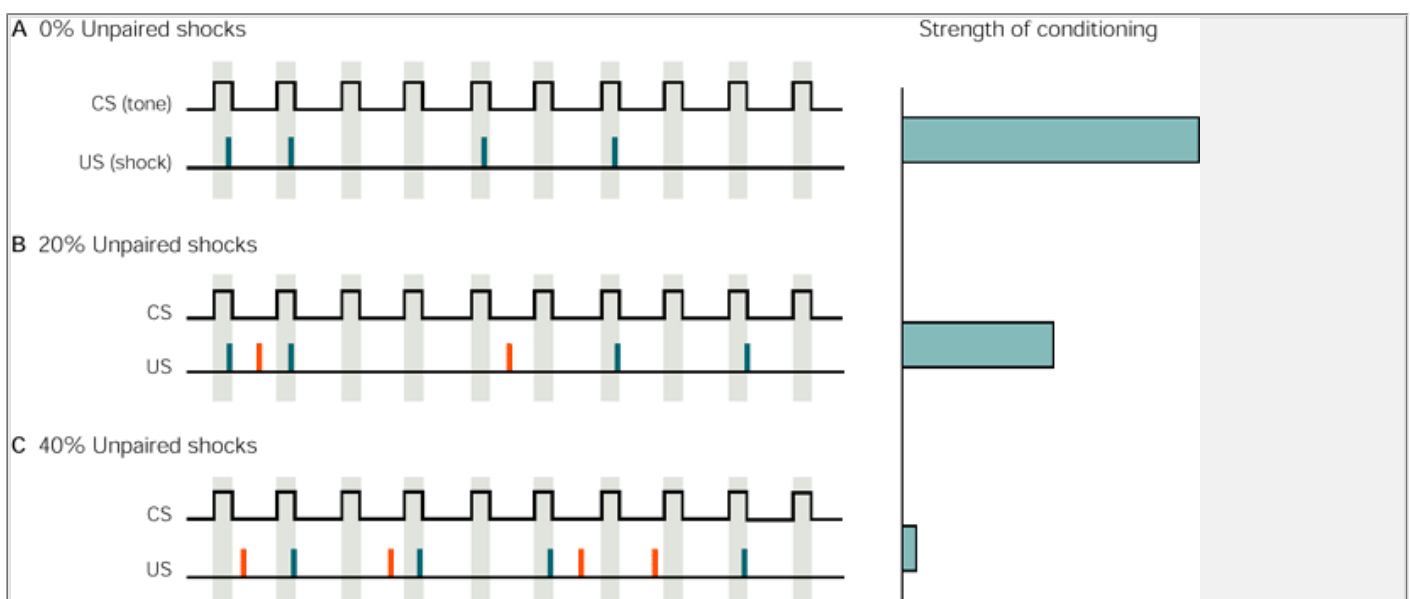

Figure 62-10 The capacity for a conditioned stimulus (CS) to produce a classically conditioned response is not a function of the number of times the CS is paired with an unconditioned stimulus (US) but rather the degree to which the CS and US are correlated. In this experiment on rats all animals were presented with a repeated tone (the CS) paired with an electric shock (the US) in 40% of the trials (blue vertical lines). Sometimes the shock was also presented when the tone was not present (red vertical lines). The percentage of these uncorrelated trials varied for different groups.

A. An experiment in which the US occurred only with the CS.

B-C. Examples in which the US was sometimes presented without the CS, either as often as the times the CS and US were paired (40%) or half as often (20%). After conditioning under the various circumstances, the degree of conditioning was evaluated by determining how effective the tone was in suppressing lever pressing to obtain food. Suppression of lever pressing is a sign of a conditioned emotional freezing response. The graph shows that in all three conditions the CS-US pairing was always 40%, but the percentage of US presentation with the absence of the CS pairing varied from 0% to 20% or 40%. When the shock occurred without the tone as often as with the tone (40%), little or no conditioning was evident. Some conditioning occurred when the shock occurred 20% of the time without the tone, and maximal conditioning occurred when the shock never occurred without the tone. (Adapted from Rescorla 1968.)

P.1241

The intensity or probability of occurrence of a conditioned response decreases if the CS is repeatedly presented without the US (Figure 62-10). This process is known as *extinction*. If a light that has been paired with food is then repeatedly presented in the absence of food, it will gradually cease to evoke salivation. Extinction is an important adaptive mechanism; it would be maladaptive for an animal to continue to respond to cues in the environment that are no longer significant. The available evidence indicates that extinction is not the same as forgetting, but that instead something new is learned. Moreover, what is learned is not simply that the CS no longer precedes the US, but that the CS now signals that the US will *not* occur.

For many years psychologists thought that classical conditioning required only contiguity, that the CS precede the US by a critical minimum time interval. According to this view, each time a CS is followed by a reinforcing stimulus or US an internal connection is strengthened between the internal representation of the stimulus and the response or between one stimulus and another. The strength of the connection was thought to depend on the number of pairings of CS and US. This theory proved inadequate, however. A substantial body of empirical evidence now indicates that classical conditioning cannot be adequately explained simply by the temporal contiguity of events (Figure 62-10). Indeed, it would be maladaptive to depend solely on temporal contiguity. If animals learned to predict one type of event simply because it repeatedly occurred with another, they might often associate events in the environment that had no utility or advantage.

All animals capable of associative conditioning, from snails to humans, seem to associate events in their environment by detecting actual *contingencies* rather than simply responding to the *contiguity* of events. Why

P.1242

is this faculty in humans similar to that in much simpler animals? One good reason is that all animals face common problems of adaptation and survival. Learning provides a successful solution to this problem, and once a successful biological solution has evolved it continues to be selected. Classical conditioning, and perhaps all forms of associative learning, may have evolved to enable animals to distinguish events that reliably and predictably occur together from those that are only randomly associated. In other words, the brain seems to have evolved mechanisms that can detect causal relationships in the environment, as indicated by positively correlated or associated events.

What environmental conditions might have shaped or maintained such a common learning mechanism in a wide variety of species? All animals must be able to recognize prey and avoid predators; they must search out food that is edible and nutritious and avoid food that is poisonous. Either the appropriate information can be genetically programmed into the animal's nervous system (as described in [Chapter 3](#)), or it can be acquired through learning. Genetic and developmental programming may provide the basis for the behaviors of simple organisms such as bacteria, but more complex organisms such as vertebrates must be capable of flexible learning to cope efficiently with varied or novel situations. Because of the complexity of the sensory information they process, higher-order animals must establish some degree of regularity in their interaction with the world. An effective means of doing this is to be able to detect causal or predictive relationships between stimuli, or between behavior and stimuli.

Operant Conditioning Involves Associating a Specific Behavior With a Reinforcing Event

A second major paradigm of associational learning, discovered by Edgar Thorndike and systematically studied by B. F. Skinner and others, is operant conditioning (also called *trial-and-error learning*). In a typical laboratory example of operant conditioning an investigator places a hungry rat or pigeon in a test chamber in which the animal is rewarded for a specific action. For example, the chamber may have a lever protruding from one wall. Because of previous learning as well as innate response tendencies and random activity, the animal will occasionally press the lever. If the animal promptly receives a positive reinforcer (eg, food) when it presses the lever, it will subsequently press the lever more often than the spontaneous rate.

The animal can be described as having learned that among its many behaviors (for example, grooming, rearing, and walking) one behavior (lever-pressing) is followed by food. With this information the animal is likely to take the appropriate action whenever it is hungry.

If we think of classical conditioning as the formation of a predictive relationship between two stimuli (the CS and the US), operant conditioning can be considered as the formation of a predictive relationship between a stimulus (eg, food) and a behavior (eg, lever pressing). Unlike classical conditioning, which tests the responsiveness of specific reflex responses to selected stimuli, operant conditioning involves behaviors that occur either spontaneously or without an identifiable stimulus. Operant behaviors are said to be *emitted* rather than elicited; when a behavior produces favorable changes in the environment (when it is rewarded or leads to the removal of noxious stimuli) the animal tends to repeat the behavior. In general, behaviors that are rewarded tend to be repeated, whereas behaviors followed by aversive, though not necessarily painful, consequences (punishment or negative reinforcement) are usually not repeated. Many experimental psychologists feel that this simple idea, called the *law of effect*, governs much voluntary behavior.

Because operant and classical conditioning involve different kinds of association—classical conditioning involves learning an association between two stimuli whereas operant conditioning involves learning the association between a behavior and a reward—one might suppose the two forms of learning are mediated by different neural mechanisms. However, the laws of operant and classical conditioning are quite similar, suggesting that the two forms of learning may use the same neural mechanisms.

For example, timing is critical in both forms of conditioning. In operant conditioning the reinforcer usually must closely follow the operant behavior. If the reinforcer is delayed too long, only weak conditioning occurs. The optimal interval between behavior and reinforcement depends on the specific task and the species. Similarly, classical conditioning is generally poor if the interval between the conditioned and unconditioned stimuli is too long or if the unconditioned stimulus precedes the conditioned stimulus. In addition, predictive relationships are equally important in both types of learning. In classical conditioning the subject learns that a certain stimulus predicts a subsequent event; in operant conditioning the animal learns to predict the consequences of a behavior.

Associative Learning Is Not Random But Is Constrained by the Biology of the Organism

For many years it was thought that associative learning could be induced simply by pairing any two arbitrarily chosen stimuli or any response and reinforcer.

More recent

P.1243

studies have shown that associative learning is constrained by important biological factors.

As we have seen, animals generally learn to associate stimuli that are relevant to their survival. This feature of associative learning illustrates nicely a principle we encountered in the earlier chapters on perception. The brain is not a *tabula rasa*; it is capable of perceiving some stimuli and not others. As a result, it can discriminate some relations between things in the environment and not others. Thus, not all reinforcers are equally effective with all stimuli or all responses. For example, animals learn to avoid certain foods (called *bait shyness*, because animals in their natural environment learn to avoid bait foods that contain poisons). If a distinctive taste stimulus (eg, vanilla) is followed by a negative reinforcement (eg, nausea produced by a poison), an animal will quickly develop a strong aversion to the taste. Unlike most other forms of conditioning, food aversion develops even when the unconditioned response (poison-induced nausea) occurs after a long delay (up to hours) after the CS (specific taste). This makes biological sense, since the ill effects of naturally occurring toxins usually follow ingestion only after some delay.

For most species, including humans, food-aversion conditioning occurs only when taste stimuli are associated with subsequent illness, such as nausea and malaise. Food aversion develops poorly, or not at all, if the taste is followed by a nociceptive, or painful, stimulus that does not produce nausea. Conversely, an animal will not develop an aversion to a distinctive visual or auditory stimulus that has been paired with nausea. Evolutionary pressures have predisposed the brains of different species to associate certain stimuli, or a certain stimulus and a behavior, much more readily than others. Genetic and experiential factors can also modify the effectiveness of a reinforcer in one species. The results obtained with a particular class of reinforcer vary enormously among species and among individuals within a species, particularly in humans

Food aversion may be a means by which humans ordinarily learn to regulate their diets to avoid the unpleasant consequences of inappropriate food. It may also be induced in special circumstances, as in the malaise associated with certain forms of cancer chemotherapy. Aversive conditioning to foods in the ordinary diet of patients might account in part for the depressed appetite of many patients who have cancer. The nausea that follows chemotherapy for cancer can produce aversion to foods that were tasted shortly before the treatment.

Certain Forms of Implicit Memory Involve the Cerebellum and Amygdala

Lesions in several regions of the brain that are important for implicit types of learning affect simple classically conditioned responses. The best-studied case is classical conditioning of the protective eyeblink reflex in rabbits, a specific form of motor learning. A conditioned eyeblink can be established by pairing an auditory stimulus with a puff of air to the eye, which causes an eyeblink. Richard Thompson and his colleagues found that the conditioned response (eyeblink in response to a tone) can be abolished by a lesion at either of two sites. Damage to the vermis of the cerebellum, even a region as small as 2 mm² abolishes the conditioned response, but does not affect the unconditioned response (eyeblink in response to a puff of air). Interestingly, neurons in the same area of the cerebellum show learning-dependent increases in activity that closely parallel the development of the conditioned behavior. Second, a lesion in the interpositus nucleus, a deep cerebellar nucleus, also abolishes the conditioned eyeblink. Thus, both the vermis and the deep nuclei of the cerebellum play an important role in conditioning the eyeblink, and perhaps other simple forms of classical conditioning involving skeletal muscle movement.

Maseo Ito and his colleagues have shown that the cerebellum is involved in another form of implicit memory. The vestibulo-ocular reflex keeps the visual image fixed by moving the eyes when the head moves ([Chapter 41](#)). The speed of movement of the eyes in relation to that of the head (the gain of the reflex) is not fixed but can be modified by experience. For example, when one first wears magnifying spectacles, eye movements evoked by the vestibulo-ocular reflex are not large enough to prevent the image from moving across the retina. With experience, however, the gain of the reflex gradually increases and the eye can again track the image accurately. As with eyeblink conditioning, the learned changes in the vestibulo-ocular reflex require not only the cerebellum (the flocculus) but also one of the deep cerebellar nuclei (the vestibular) in the brain stem (see [Chapters 41](#) and [42](#)). Finally, as we have seen in [Chapter 50](#), lesions of the amygdala impair conditioned fear.

Some Learned Behaviors Involve Both Implicit and Explicit Forms of Memory

Classical conditioning, we have seen, is effective in associating an unconscious reflexive response with a particular stimulus and thus typically involves implicit forms of memory. However, even this simple form of learning may also involve explicit memory, so that the learned response is mediated at least in part by cognitive processes. Consider the following experiment. A subject lays her hand, palm down, on an electrified grill;

P.1244

a light (the CS) is turned on and at the same time she receives an electrical shock on one finger—she lifts her hand immediately (unconditioned response). After several light-shock conditioning trials she lifts her hand when the light alone is presented. The subject has been conditioned; but what exactly has been conditioned?

Figure 62-11 Recent memories are more susceptible than older memories to disruption by electroconvulsive treatment (ECT). The plot shows the responses of a group of patients who were tested on their ability to recall the names of television programs that were on the air during a single year between 1957 and 1972. Testing was done before and after the patients received ECT for treatment of depression. After ECT the patients showed a significant (but transitory) loss of memory for recent programs (1-2 years old) but not for older programs. (Adapted from [Squire et al. 1975](#).)

It appears that the light is triggering a specific pattern of muscle activity (a *reflex*) that lifts the hand. However, what if the subject now places her hand on the grill, palm up, and the light is presented? If a specific reflex has been conditioned the light should produce a response that moves the hand *into* the grill. But if the subject has acquired information that the light means “grill shock,” her response should be consistent with that information. In fact, the subject often will make an *adaptive response* and move her hand away from the grill. Therefore, the subject did not simply learn to apply a fixed response to a stimulus, but rather acquired information that the brain could use in shaping an appropriate response in a novel situation.

As this example makes clear, learning usually has elements of both implicit and explicit learning. For instance, learning to drive an automobile involves conscious execution of specific sequences of motor acts necessary to control the car; with experience, however, driving becomes an automatic and nonconscious motor activity. Similarly, with repeated exposure to a fact (*semantic learning*), recall of the fact with appropriate clues can eventually become virtually instantaneous—we no longer consciously and deliberately search our memory for it.

Both Explicit and Implicit Memory Are Stored in Stages

It has long been known that a person who has been knocked unconscious selectively loses memory for events that occurred before the blow (retrograde amnesia). This phenomenon has been documented thoroughly in animal studies using such traumatic agents as electroconvulsive shock, physical trauma to the brain, and drugs that depress neuronal activity or inhibit protein synthesis in the brain. Brain trauma in humans can produce particularly profound amnesia for events that occur within a few hours or, at most, days before the trauma. In such cases older memories remain relatively undisturbed. The extent of retrograde amnesia, however, varies among patients, from several seconds to several years, depending on the nature and strength of the learning and the nature and severity of the disrupting event.

Studies of memory retention and disruption of memory have supported a commonly used model of memory storage by stages. Input to the brain is processed into short-term working memory before it is transformed through one or more stages into a more permanent long-term store. A search-and-retrieval system surveys the memory store and makes information available for specific tasks.

According to this model, memory can be impaired at several points. For example, there can be a loss of the contents of a memory store; as we have seen ([Chapter 58](#)), in Alzheimer's disease there actually is a loss of nerve cells in the entorhinal cortex. Alternatively, the search-and-retrieval mechanism may be disrupted by head trauma. This latter conclusion is supported by the observation that trauma sometimes only temporarily disrupts memory, since considerable memory for past events gradually returns. If stored memory were completely lost, it obviously could not be recovered.

Studies of memory loss in patients undergoing electroconvulsive therapy (ECT) for depression have confirmed and extended the findings from animal experiments. Patients were examined using a memory test that could reliably quantify the degree of memory for relatively recent events (1-2 years old), old events (3-9 years old), and very old events (9-16 years old). The patients

P.1245

were asked to identify, by voluntary recall, the names of television programs broadcast during a single year between 1957 and 1972. The patients were tested before ECT and then again afterward (with a different set of television programs). Both before and after ECT recall of the programs was more correct for more recent years. After ECT, however, the patients showed a significant but transitory loss of memory for more recent programs, while their recall of older programs remained essentially the same as it was before ECT ([Figure 62-11](#)).

One interpretation of these findings is that until memories have been converted to a long-term form, retrieval (recall) of recent memories is easily disrupted.

Once converted to a long-term form, however, the memories are relatively stable. With time, however, both the long-term memory and the capacity to retrieve it gradually diminish, even in the absence of external trauma. Because of this susceptibility to disruption, the total set of retrievable memories changes continually with time.

Several experiments studying the effects of drugs on learning support the idea that memory is time-dependent and subject to modification when it is first formed. For example, subconvulsant doses of excitant drugs, such as strychnine, can improve the retention of learning of animals even when the drug is administered after the training trials. If the drug is given to the animal soon after training, retention of learning on the following day is greater. The drug has no effect, however, when given after a long delay (several hours) after training. In contrast, inhibitors of protein synthesis selectively block the formation of long-term memory but not short-term memory when given during the training procedure.

An Overall View

The neurobiological study of memory has yielded three generalizations: memory has stages, long-term memory is represented in multiple regions throughout the nervous system, and explicit and implicit memories involve different neuronal circuits.

Different types of memory processes involve different regions and combinations of regions in the brain. Explicit memory underlies the learning of facts and experiences—knowledge that is flexible can be recalled by conscious effort and can be reported verbally. Implicit memory processes include forms of perceptual and motor memory—knowledge that is stimulus-bound, is expressed in the performance of tasks without conscious effort, and is not easily expressed verbally. Implicit memory flows automatically in the doing of things, while explicit memory must be retrieved deliberately.

Long-term storage of explicit memory requires the temporal lobe system. Implicit memory involves the cerebellum and amygdala and the specific sensory and motor systems recruited for the task being learned. Moreover, the memory processes for many types of learning involve several brain structures. For example, learned changes of the vestibulo-ocular reflex appear to involve at least two different sites in the brain, and explicit learning involves neocortical structures as well as the hippocampal formation. Furthermore, there are reasons to believe that information is represented at multiple sites even within one brain structure.

This parallel processing may explain in part why a limited lesion often does not eliminate a specific memory, even a simple implicit memory. Another important factor that may account for the failure of small lesions to adversely affect a specific memory may reside in the very nature of learning. As we shall see in the next chapter, memory involves both functional and structural changes at synapses in the circuits participating in a learning task. Although such changes are likely to occur only in particular types of neurons, the complex nature of many tasks makes it likely that these neurons are widely distributed within the pathways that mediate the response. Therefore some components of the stored information (ie, some of the synaptic changes) could remain undisturbed by a small lesion. Furthermore, the brain can take even the limited store of remaining information and construct a good representation of the original, just as the brain normally constructs conscious memory.

Cellular Mechanisms of Learning and the Biological Basis of Individuality

Eric R. Kandel

THROUGHOUT THIS BOOK we have emphasized that all behavior is a function of the brain and that malfunctions of the brain give rise to characteristic disturbances of behavior. Behavior, in turn, is shaped by learning. How does learning act on the brain to change behavior? How is new information acquired and, once acquired, how is it retained? In the preceding chapter we saw that memory—the outcome of learning—is not a single process but has at least two forms. *Implicit* (declarative) *memory* is unconscious memory for perceptual and motor skills, whereas *explicit* (nondeclarative) *memory* is a memory for people, places, and objects that requires conscious recall.

In this chapter we examine the cellular and molecular mechanisms that contribute to these two forms of memory by exploring the mechanisms that underlie simple implicit forms of memory storage in invertebrates and the more complex explicit forms in vertebrates. We shall see that the molecular mechanisms of memory storage are highly conserved throughout evolution, and that the more complex forms of learning and memory depend on many of the same molecular mechanisms used in the simplest forms. Finally, we shall consider the idea that these mechanisms contribute to individuality by changing the connectivity of neurons in our brains.

Figure 63-1 The cellular mechanisms of habituation have been investigated in the gill-withdrawal reflex of the marine snail *Aplysia*.

A. A dorsal view of *Aplysia* illustrates the respiratory organ (gill), which is normally covered by the mantle shelf. The mantle shelf ends in the siphon, a fleshy spout used to expel seawater and waste. A tactile stimulus to the siphon elicits the gill-withdrawal reflex. Repeated stimuli lead to habituation.

B. This simplified circuit shows key elements involved in the gill-withdrawal reflex as well as sites involved in habituation. In this circuit about 24 mechanoreceptors in the abdominal ganglion innervate the siphon skin. These glutaminergic sensory cells form synapses with a cluster of six motor neurons that innervate the gill and with several groups of excitatory and inhibitory interneurons that synapse on the motor neurons. (For simplicity, only one of each type of neuron is illustrated here.) Repeated stimulation of the siphon leads to a depression of synaptic transmission between the sensory and motor neurons as well as between certain interneurons and the motor cells.

Short-Term Storage of Implicit Memory for Simple Forms of Learning Results From Changes in the Effectiveness of Synaptic Transmission

Much progress in the cellular study of memory storage has come from examining elementary forms of learning: habituation, sensitization, and classical conditioning. These cellular modifications have been analyzed in the behavior of simple invertebrates and in a variety of vertebrate reflexes, such as flexion reflexes, fear responses, and the eyeblink. Most simple forms of implicit learning change the effectiveness of the synaptic connections that make up the pathway mediating the behavior.

Habituation Involves an Activity-Dependent Presynaptic Depression of Synaptic Transmission

In *habituation*, the simplest form of implicit learning, an animal learns about the properties of a novel stimulus that is harmless. An animal first responds to a new stimulus by attending to it with a series of orienting responses. If the stimulus is neither beneficial nor harmful, the animal learns, after repeated exposure, to ignore it.

Habituation was first investigated by Ivan Pavlov and Charles Sherrington. While studying posture and locomotion, Sherrington observed a decrease in the intensity of certain reflexes, such as the withdrawal of a limb, in response to repeated stimulation. The reflex response returned only after many seconds of rest. He suggested that this decrease, which he called habituation, results from diminished synaptic effectiveness within the pathways to the motor neurons that had been repeatedly activated.

This problem was later investigated at the cellular level by Alden Spencer and Richard Thompson. They found close cellular and behavioral parallels between habituation of the spinal flexion reflex in the cat and habituation of more complex behavioral responses in humans. They showed, through intracellular recordings from spinal motor neurons in cats, that habituation leads to a decrease in the strength of the synaptic connections between excitatory interneurons and motor neurons. The connections between the sensory neurons innervating the skin and the interneurons were unaffected.

Since the organization of interneurons in the spinal cord of vertebrates is quite complex, further analysis of the cellular mechanisms of habituation in the flexion reflex proved difficult. Progress in this effort required a simpler system. The marine sea slug *Aplysia californica*, which has a simple nervous system containing only about 20,000 central nerve cells, is an excellent simple system for studying implicit forms of memory. *Aplysia*

P.1249

has a repertory of defensive reflexes for withdrawing its gill and its siphon, a small fleshy spout above the gill used to expel seawater and waste (Figure 63-1A). These reflexes are similar to the leg withdrawal reflex studied by Spencer and Thompson. For example, a mild tactile stimulus delivered to the siphon elicits reflex withdrawal of both siphon and gill. With repeated stimulation these reflexes habituate. They can also be sensitized and classically conditioned, as we shall see later.

Gill withdrawal in *Aplysia* has been studied in detail. In response to a novel tactile stimulus to the siphon, firing in the sensory neurons innervating the siphon generates excitatory synaptic potentials in interneurons and motor cells (Figure 63-1B). The synaptic potentials from the sensory neurons and interneurons summate both temporally and spatially to cause the motor cells to discharge repeatedly, leading to strong reflexive withdrawal of the gill. If the stimulus is repeated, the direct monosynaptic excitatory synaptic potentials produced by sensory neurons in both the interneurons and the motor cells become progressively smaller. Thus, with repeated stimulation, several of the excitatory interneurons also produce weaker synaptic potentials in the motor neurons, with the net result that the motor neuron fires much less briskly and consequently the reflex response diminishes.

What reduces the effectiveness of synaptic transmission by the sensory neurons? Quantal analysis revealed that the decrease in synaptic strength results from a decrease in the number of transmitter vesicles released from presynaptic terminals of sensory neurons. These sensory neurons use glutamate as their transmitter. Glutamate interacts with two types of receptors in motor cells: one similar to the *N*-methyl-d-aspartate (NMDA) type of glutamate receptors of vertebrates and the other to a non-NMDA-type (Chapter 12). There is no change in the sensitivity of these receptors with habituation. How this decrease in transmitter release occurs is not yet understood; it is thought to be due in part to a reduced mobilization of transmitter vesicles to the active zone (see Chapter 14). This reduction lasts many minutes.

These enduring *plastic* changes in the functional strength of synaptic connections thus constitute the cellular mechanisms mediating the short-term memory for habituation. Since these changes occur at several sites in the reflex circuit, memory in this instance is distributed and stored throughout the circuit, not at one specialized site. Synaptic depression of the connections made by sensory neurons, interneurons, or both is a common mechanism for habituation and explains habituation of the several well-studied escape responses of crayfish and cockroaches as well as startle reflexes of vertebrates.

Figure 63-2 Long-term habituation of the gill-withdrawal reflex in *Aplysia* is represented on the cellular level by a dramatic depression of synaptic effectiveness between the sensory and motor neurons. (Adapted from Castellucci et al. 1978.)

A. Comparison of the synaptic potentials in a sensory and motor neuron in a control (untrained) animal and an animal that has been subjected to long-term habituation. In the habituated animal no synaptic potential is evident in the motor neuron one week after training.

B. The mean percentage of physiologically detectable connections in habituated animals at three points in time after long-term habituation training.

The synaptic mechanisms underlying habituation can vary in two ways. First, the locus of the depression can be situated at any of several synaptic sites. For example, in the flexion reflex of the spinal cord there is no depression of synaptic transmission at the direct connections made by the sensory neurons on interneurons.

P.1250

Rather, depression is thought to occur at downstream sites: at the synapses made by certain classes of interneurons on the motor neurons of the reflex. Second, mechanisms other than homosynaptic depression, such as enhancement of synaptic inhibition, can contribute to habituation.

These studies illustrate that learning can lead to changes in synaptic strength and that the duration of the short-term memory storage is determined by the duration of the synaptic change. In turn, these studies raise the question: How much can the effectiveness of a synapse change and how long can the change last? Whereas a single session of 10 tactile stimuli to the siphon leads to a short-term memory for habituation of the *Aplysia* gill-withdrawal reflex lasting minutes, four such sessions, separated by periods ranging from several hours to one day, produce a long-term memory that lasts for as long as three weeks! In naive *Aplysia* 90% of the sensory neurons make physiologically detectable connections onto identified gill motor neurons. In contrast, in animals trained for long-term habituation the number of such connections is reduced to 30%; this low incidence persists for a week and does not completely recover for three weeks after the training (Figure 63-2). As we shall see later, during this long-term inactivation of synaptic transmission the actual structure of the sensory neurons changes.

Not all synapses are equally adaptable. The strength of some synapses in *Aplysia* rarely changes, even with repeated activation. However, at synapses specifically involved in learning and memory storage, such as the connections between sensory and motor neurons and some interneurons in the withdrawal-reflex circuit, a relatively small amount of training, especially if it is appropriately spaced over many minutes or hours, can produce large and enduring changes in synaptic strength. Massed training, whereby the habituating stimuli are given one after the other without rest between training sessions, produces a robust short-term memory but long-term memory is seriously compromised. This illustrates a general principle of learning psychology: Spaced training is usually much more effective than massed training in producing long-term memory.

Sensitization Involves Presynaptic Facilitation of Synaptic Transmission

When an animal repeatedly encounters a harmless stimulus it learns to habituate to it. In contrast, with a *harmful* stimulus the animal typically learns to respond more vigorously not only to that stimulus but also to other stimuli, even harmless ones. Defensive reflexes for withdrawal and escape become heightened. This enhancement of reflex responses, called *sensitization*, is more complex than habituation: A stimulus applied to one pathway produces a change in the reflex strength in another pathway. Like habituation, sensitization has both a short-term and a long-term form. Thus, whereas a single shock to an animal's tail produces short-term sensitization that lasts minutes, five or more shocks to the tail produce sensitization lasting days to weeks.

A noxious stimulus to the tail enhances synaptic transmission at several connections in the neural circuit of the gill-withdrawal reflex, including the connections made by sensory neurons with motor neurons and interneurons—the same synapses depressed by habituation. Thus a synapse can participate in more than one type of learning and store more than one type of memory. However, habituation and sensitization use different cellular mechanisms to produce synaptic change. Short-term habituation in *Aplysia* is a *homosynaptic process*; the decrease in synaptic strength is a direct result of activity in the sensory neurons and their central connections in the reflex pathway. In contrast, sensitization is a *heterosynaptic process*; the enhancement of

P.1251

P.1252

synaptic strength is induced by modulatory interneurons activated by stimulation of the tail.

Figure 63-3 (Opposite) Short-term sensitization of the gill-withdrawal reflex in *Aplysia* involves presynaptic facilitation.

A. Sensitization of the gill is produced by applying a noxious stimulus to another part of the body, such as the tail. Stimuli to the tail activate sensory neurons in the tail that excite facilitating interneurons, which form synapses on the terminals of the sensory neurons innervating the siphon. At these axoaxonic synapses the facilitating interneurons enhance transmitter release from the sensory neurons (*presynaptic facilitation*).

B. Presynaptic facilitation in the sensory neuron is thought to occur by means of three biochemical pathways. The transmitter released by the presynaptic interneuron, here serotonin (**5-HT**, hydroxytryptamine), binds to two receptors. One engages a G protein (**G_s**), which increases the activity of adenylyl cyclase. The adenylyl cyclase converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (**cAMP**), thereby increasing the level of cAMP in the terminal of the sensory neuron. The cAMP activates the cAMP-dependent protein kinase A (**PKA**) by attaching to its inhibitory regulatory subunit, thus releasing its active catalytic subunit.

The catalytic subunit of PKA acts along three pathways. In **pathway 1** the catalytic subunit phosphorylates K⁺ channels, thereby decreasing the K⁺ current. This prolongs the action potential and increases the influx of Ca²⁺, thus augmenting transmitter release. In **pathway 2** vesicles containing transmitter are mobilized to the releasable transmitter pool at the active zone, and the efficiency of the exocytotic release machinery is also enhanced. In **pathway 3** L-type Ca²⁺ channels are opened. Serotonin, acting through a second receptor, engages the G protein (**G_o**) that activates a phospholipase C (**PLC**), which in turn stimulates intramembranous diacylglycerol to activate protein kinase C (**PKC**). **Pathways 2-2a** and **3-3a** involve the joint action of PKA and PKC.

There are at least three groups of modulatory inter-neurons, the best studied of which release serotonin. The serotonergic and other modulatory interneurons form synapses on the sensory neurons, including axo-axonic synapses on their presynaptic terminals ([Figure 63-3A](#)). The serotonin and other modulatory transmitters released from the interneurons after a single shock to the tail bind to specific membrane-spanning receptors that activate the heterotrimeric GTP binding protein G_{αs}. The G_{αs} protein activates an adenylyl cyclase to produce the second messenger cyclic adenosine mono-phosphate (cAMP), which activates the cAMP-dependent protein kinase (PKA) (see the discussion of PKA in [Chapter 13](#)). PKA, together with protein kinase C, enhances release of transmitter from the sensory neurons' terminals for a period of minutes through the phosphorylation of several substrate proteins ([Figure 63-3B](#)). As we shall learn later, repeated sensitizing stimuli produce a strengthening of connections that lasts days.

Classical Conditioning Involves Presynaptic Facilitation of Synaptic Transmission That Is Dependent on Activity in Both the Presynaptic and the Postsynaptic Cell

Classical conditioning is a more complex form of learning than sensitization. Rather than learning only about one stimulus, the organism learns to associate one type of stimulus with another. As we have learned in [Chapter 62](#), an initially weak conditioned stimulus can become highly effective in producing a response when paired with a strong unconditioned stimulus. In reflexes that can be enhanced by both classical conditioning and sensitization, classical conditioning results in a greater and longer-lasting enhancement.

The siphon- and gill-withdrawal reflexes of *Aplysia* are examples of reflexes that can be enhanced by both classical conditioning and sensitization. The gill-withdrawal reflex can be elicited in one of two ways: by stimulating either the siphon or a nearby structure called the *mantle shelf*. The siphon and the mantle shelf are separately innervated by distinct populations of sensory neurons. Thus, each reflex pathway can be conditioned independently by pairing a conditioned stimulus to the appropriate area (either the siphon or the mantle shelf) with an unconditioned stimulus (a strong shock to the tail). After such paired or associative training, the response of the conditioned (or paired) pathway to stimulation is significantly enhanced compared to that of the unpaired pathway ([Figure 63-4](#)).

In classical conditioning the timing of the conditioned and unconditioned stimuli is critical. The conditioned stimulus must *precede* the unconditioned stimulus, often within an interval of about 0.5 s. What cellular mechanisms are responsible for this requirement for temporal pairing of stimuli? In classical conditioning of the gill-withdrawal reflex of *Aplysia* one important feature is the timing of the convergence in individual sensory neurons of the conditioned stimulus (siphon touch) and the unconditioned stimulus (tail shock).

As we have seen, an unconditioned stimulus to the tail activates facilitating interneurons that make axo-axonic connections with the presynaptic terminals of the sensory neurons that carry information from the siphon and the mantle shelf ([Figure 63-4A](#)). The resulting presynaptic facilitation ordinarily gives rise to behavioral sensitization. However, if the unconditioned stimulus (to the tail) and the conditioned stimulus (to the siphon or mantle shelf) are timed so that the conditioned stimulus just precedes the unconditioned stimulus, then the modulatory interneurons engaged by the unconditional stimulus will activate the sensory neurons immediately *after* the conditioned stimulus has activated the sensory neurons. This sequential activation of the sensory neurons during a critical interval by the CS and the US leads to greater presynaptic facilitation than when the two stimuli are not appropriately paired ([Figure 63-4B](#)). This novel feature unique to classical conditioning is called activity dependence.

There are presynaptic and postsynaptic components to activity-dependent facilitation. Activity in the conditioned stimulus pathway leads to Ca^{2+} influx into the presynaptic sensory neuron with each action potential, and this influx activates the Ca^{2+} -binding protein calmodulin. The activated Ca^{2+} /calmodulin binds to adenylyl cyclase, potentiating its response to serotonin and enhancing its production of cAMP. Thus, the presynaptic cellular mechanism of classical conditioning in the monosynaptic pathway of the withdrawal reflex in *Aplysia* is in part an elaboration of the mechanism of sensitization in this same pathway. This is because adenylyl cyclase acts as a *coincidence detector*. That is, it recognizes the molecular representation of both the conditioned stimulus (spike activity in the sensory neuron and the consequent Ca^{2+} influx) and the unconditioned stimulus (serotonin released by tail stimuli), and it responds both to the conditioned stimulus (binding to the Ca^{2+} /calmodulin activated by the Ca^{2+} /influx following action potentials) and the unconditioned stimulus (binding to the $G_{\alpha s}$ activated by the binding of serotonin to a receptor).

The postsynaptic component of classical conditioning is a retrograde signal to the sensory neuron. In the withdrawal reflex pathway in *Aplysia* the postsynaptic motor cell has two types of receptors to glutamate: nonNMDA and NMDA-type receptors. As we have learned in [Chapter 11](#), the extracellular mouth of the NMDA-type receptor-channel is plugged by Mg^{2+} at the resting membrane potential. Thus, under normal circumstances and during habituation and sensitization only the non-NMDA receptor is activated because the NMDA receptor is blocked by Mg^{2+} . However, when the conditioned stimulus and unconditioned stimulus are paired appropriately during classical conditioning, the motor neuron fires a whole train of action potentials. The depolarization of the postsynaptic cell expels Mg^{2+} from the NMDA-type receptor-channel and Ca^{2+} flows into the cell. The Ca^{2+} influx is thought to activate signaling pathways in the motor cell that give rise to a retrograde messenger that is taken up in the presynaptic terminals of the sensory cell, where it acts to enhance transmitter release even further.

P.1253

receptor-channel is plugged by Mg^{2+} at the resting membrane potential. Thus, under normal circumstances and during habituation and sensitization only the non-NMDA receptor is activated because the NMDA receptor is blocked by Mg^{2+} . However, when the conditioned stimulus and unconditioned stimulus are paired appropriately during classical conditioning, the motor neuron fires a whole train of action potentials. The depolarization of the postsynaptic cell expels Mg^{2+} from the NMDA-type receptor-channel and Ca^{2+} flows into the cell. The Ca^{2+} influx is thought to activate signaling pathways in the motor cell that give rise to a retrograde messenger that is taken up in the presynaptic terminals of the sensory cell, where it acts to enhance transmitter release even further.

Figure 63-4 Classical conditioning of the gill-withdrawal reflex in *Aplysia*. A conditioned stimulus (CS) applied to the mantle shelf is paired with an unconditioned stimulus (US) applied to the tail. As a control, a CS applied to the siphon is not paired with the US. (Adapted from [Hawkins et al. 1983.](#))

A. A shock to the tail (US) excites facilitating interneurons that form synapses on the presynaptic terminals of sensory neurons innervating the mantle shelf and siphon. This is the mechanism of sensitization (A1).

B. When the mantle pathway is activated by a CS just before the US, the action potentials in the mantle sensory neurons prime them so that they are more responsive to subsequent stimulation from the (serotonergic) facilitating interneurons in the US pathway. This is the mechanism of classical conditioning; it both amplifies the response of the CS pathway and restricts the amplification to that pathway (B1).

Recordings of the excitatory postsynaptic potentials produced in an identified motor neuron by the mantle and siphon sensory neurons were made before training (Pre) and 1 hour after training (Post). After training the excitatory postsynaptic potential due to input from the mantle (paired) sensory neuron (B2) is considerably greater than the one due to the siphon (unpaired) neuron (A2).

C. The experimental protocol for classical conditioning compares the responses of paired and unpaired stimuli mediated by siphon and mantle sensory neurons. In the mantle sensory neurons the action potentials produced by the CS are paired with those produced by the US (tail stimulus). In a siphon sensory neuron the action potentials produced by the CS are not paired with the same US.

Thus, three signals in a siphon sensory neuron must converge to produce the large increase in transmitter release that occurs with classical conditioning: (1) activation

receptors coupled to adenylyl cyclase, representing the unconditioned stimulus; and (3) a retrograde signal indicating that the postsynaptic cell has been adequately activated by the unconditioned stimulus.

Long-Term Storage of Implicit Memory for Sensitization and Classical Conditioning Involves the cAMP-PKA-MAPK-CREB Pathway

Molecular Biological Analysis of Long-Term Sensitization Reveals a Role for cAMP Signaling in Long-Term Memory

As with habituation and most other forms of learning, practice makes perfect. Repeated experience consolidates memory by converting the short-term form into a long-term form. These physiological consequences of repeated training have been best studied for sensitization. In *Aplysia* a single training session (or a single application of serotonin to the sensory neurons) gives rise to short-term sensitization, lasting only minutes, that does not require new protein synthesis. However, five training sessions produce long-term sensitization, lasting several days, that requires new protein synthesis. Further spaced training produces sensitization that persists for weeks. These behavioral studies of *Aplysia* (and similar ones in vertebrates) suggest that short-term and long-term memory are two independent but overlapping processes that blend into one another. Several findings point to this interpretation.

First, both short- and long-term memory for sensitization of the gill-withdrawal reflexes involve changes in the strength of connections at several synaptic sites, including the synaptic connections between sensory and motor neurons (Figure 63-5A). Second, in both the long-term and short-term processes the increase in the synaptic strength of the connections between the sensory and motor neurons is due to the enhanced release of transmitter. Third, the same transmitter (serotonin) released by stimulation of the tail produces short-term facilitation after a single exposure and long-term facilitation after five or more repeated exposures. Finally, cAMP and PKA, intracellular second-messenger pathways that are critically involved in short-term memory, are also recruited for long-term memory (Figure 63-5B).

Despite these similarities, short- and long-term memory are distinct processes that can be distinguished by several criteria. In humans, epileptic seizure or head trauma affects long-term memory but not short-term memory. A similar dissociation between short- and long-term memory can be demonstrated in experimental animals using inhibitors of protein or mRNA synthesis to block long-term memory selectively.

As we saw in the preceding chapter, the process by which transient short-term memory is converted into a stable long-term memory is called *consolidation*. Consolidation of long-term implicit memory for simple forms

of learning involves three processes: gene expression, new protein synthesis, and the growth (or pruning) of synaptic connections.

Figure 63-5 (Facing page) Persistent synaptic enhancement with long-term sensitization.

A. Long-term sensitization of the gill-withdrawal reflex of *Aplysia* involves facilitation of transmitter release at the connections between sensory and motor neurons. **1.** The recordings show representative synaptic potentials in a siphon sensory neuron and a gill motor neuron in a control animal and in an animal that received long-term sensitization training by repeated stimulation of its tail. The record was obtained one day after the end of training. **2.** The median amplitude of the post-synaptic potentials (**PSP**) in an identified gill motor neuron is greater in sensitized animals one day after training than in control animals. **3.** The effect of sensitization on the neural circuit of the gill- and siphon-withdrawal reflex is measured here by the median duration of withdrawal of the siphon (see [Figure 63-1](#)). (**Pre** = score before training; **post** = score after training.) The experimental group was tested one day after the end of training. (Adapted from [Frost et al. 1985](#).)

B. Long-term sensitization of the gill-withdrawal reflex of *Aplysia* leads to two major changes in the sensory neurons of the reflex: persistent activity of protein kinase A and structural changes in the form of the growth of new synaptic connections.

Both the short-term and long-term facilitation are initiated by a serotonergic interneuron. Short-term facilitation (lasting minutes to hours), resulting from a single tail shock or a single pulse of serotonin, leads to covalent modification of preexisting proteins (short-term pathway). As shown in [Figure 63-3](#), serotonin acts on a postsynaptic receptor to activate the enzyme adenylyl cyclase, which converts ATP to the second messenger cAMP. In turn, cAMP activates the cAMP-dependent protein kinase A, which phosphorylates and covalently modifies a number of target proteins, leading to enhanced transmitter availability and release. The duration of these modifications is a measure of the short-term memory.

Long-term facilitation (lasting one or more days) involves the synthesis of new proteins. The switch for this inductive mechanism is initiated by protein kinase A (**PKA**), which recruits the mitogen-activated kinase (**MAPK**) and together they translocate to the nucleus (long-term pathway), where PKA phosphorylates the cAMP-response element binding (**CREB**) protein. The transcriptional activators bind to cAMP response elements (**CRE**) located in the upstream region of two types of cAMP-inducible genes. To activate CREB-1, PKA needs also to remove the repressive action of CREB-2, which is capable of inhibiting the activation capability of CREB-1. PKA is thought to mediate the derepression of CREB-2 by means of another protein, MAPK. One gene activated by CREB encodes a ubiquitin hydrolase, a component of a specific ubiquitin protease that leads to the regulated proteolysis of the regulatory subunit of PKA. This cleavage of the (inhibitory) regulatory subunit results in persistent activity of PKA, leading to persistent phosphorylation of the substrate proteins of PKA, including both CREB-1 and the protein involved in the short-term process. The second gene activated by CREB encodes another transcription factor **C/EBP**. This binds to the DNA response element **CAAT**, which activates genes that encode proteins important for the growth of new synaptic connections.

Figure 63-6 Long-term habituation and sensitization in *Aplysia* involve structural changes in the presynaptic terminals of sensory neurons. (Adapted from Bailey and Chen 1983.)

A. When measured 1 day or 1 week after training, the number of presynaptic terminals is highest in sensitized animals (about 2800) compared with control (1300) and habituated animals (800).

B. Long-term habituation leads to a loss of synapses and long-term sensitization leads to an increase in synapses.

How do genes and proteins operate in the consolidation of long-term functional changes? Studies of long-term sensitization of the gill-withdrawal reflex indicate that with repeated application of serotonin the catalytic subunit of PKA recruits another second messenger kinase, the mitogen-activated protein (MAP) kinase, a kinase commonly associated with cellular growth. Together the two kinases translocate to the nucleus of the sensory neurons, where they activate a genetic switch (see the discussion of transcriptional regulation in Chapter 13). Specifically, the catalytic subunit phosphorylates and thereby activates a transcription factor called *CREB-1* (cAMP response element binding protein). This transcriptional activator, when phosphorylated, binds to a promoter element called *CRE* (the cAMP response element). By means of the MAP kinase the catalytic subunit of PKA also acts indirectly to relieve the inhibitory actions of *CREB-2*, a repressor of transcription.

The presence of both a repressor (*CREB-2*) and an activator (*CREB-1*) of transcription at the very first step in long-term facilitation suggests that the threshold for putting information into long-term memory is highly *regulated*. Indeed, we can see in everyday life that the ease with which short-term memory is transferred into long-term memory varies greatly depending on attention, mood, and social context. In fact, when the repressive action of *CREB-2* is relieved (by injecting, for example, a specific antibody to *CREB-2*), a single pulse of serotonin, which normally produces only short-term facilitation lasting minutes, is able to produce long-term facilitation, the cellular homolog of long-term memory.

Under normal circumstances the physiological relief of the repressive action of *CREB-2* and the activation of *CREB-1* induce expression of downstream target genes, two of which are particularly important: (1) the enzyme ubiquitin carboxyterminal hydrolase, which activates proteasomes to make PKA persistently active, and (2) the transcription factor C/EBP, one of the components of a gene cascade necessary for the growth of new synaptic connections. The induction of the hydrolase is a key step in the recruitment of a regulated proteolytic

P.1257

complex: the ubiquitin-dependent proteasome. As in other cellular contexts, ubiquitin-mediated proteolysis also produces a cellular change of state, here by removing inhibitory constraints on memory. One of the substrates of this proteolytic process is the regulatory subunit of PKA.

Figure 63-7 The three major afferent pathways in the hippocampus. (Arrows denote the direction of impulse flow.) The perforant fiber pathway from the entorhinal cortex forms excitatory connections with the granule cells of the dentate gyrus. The granule cells give rise to axons that form the mossy fiber pathway, which connects with the pyramidal cells in area CA3 of the hippocampus. The pyramidal cells of the CA3 region project to the pyramidal cells in CA1 by means of the Schaffer collateral pathway. Long-term potentiation (LTP) is nonassociative in the mossy fiber pathway and associative in the other two pathways.

PKA is made up of four subunits: two regulatory subunits inhibit two catalytic subunits (Chapter 13). Long-term training and the induction of the hydrolase degrades about 25% of the regulatory (inhibitory) subunits in the sensory neurons. As a result, the catalytic subunits continue phosphorylating proteins important for enhancing transmitter release and strengthening the synaptic connections, including *CREB-1*, long after the second messenger, cAMP, has returned to its basal level (Figure 63-5B). This is the simplest mechanism for long-term memory: a second-messenger kinase critical for the short-term process is made persistently active for up to 24 hours by repeated training, without requiring a continuous signal of any sort. The kinase becomes autonomous and does not require either serotonin, cAMP, or PKA.

The second and more enduring consequence of the activation of *CREB-1* is a cascade of gene activation that leads to the growth of new synaptic connections. It is this growth process that provides the stable, self-maintained state of long-term memory. In *Aplysia* the number of presynaptic terminals in the sensory neurons of the gill-withdrawal pathway increases and becomes twice as great in the long term in sensitized animals as in untrained animals (Figure 63-6). This structural change is not limited to the sensory neurons. In animals that have been sensitized for the long term, the dendrites of the motor neurons grow to accommodate the additional synaptic input. Such morphological changes do not occur with short-term sensitization. Long-term habituation, in contrast, leads to *pruning* of synaptic connections. The long-term inactivation of the functional connections between sensory and motor neurons reduces the number of terminals for each neuron by one-third (Figure 63-6), and the proportion of terminals with active zones from 40% to 10%.

Genetic Analyses of Implicit Memory Storage for Classical Conditioning Also Implicate the cAMP-PKA-CREB Pathway

How general is the role of the cAMP-PKA-CREB pathway in long-term memory storage? Does it apply to other species and other types of learning? The fruit fly *Drosophila* is particularly amenable to genetic manipulation. As first shown by Seymour Benzer and his students, *Drosophila* can be classically conditioned, and four interesting mutations in single genes that lead to a learning deficit have been isolated: *dunce*, *rutabaga*, *amnesiac*, and *PKA-R1*. Studies of these mutants have given

rise to two general conclusions. First, all of the mutants that fail to show classical conditioning also fail to show sensitization. Second, all four mutants have a defect in the cAMP cascade. *Dunce* lacks phosphodiesterase, an enzyme that degrades cAMP. As a result, this mutant has abnormally high levels of cAMP that are thought to be beyond the range of normal modulation. *Rutabaga* is defective in the Ca^{2+} /calmodulin-dependent adenylyl cyclase and therefore has a low basal level of cAMP. *Amnesiac* lacks a peptide transmitter that acts on adenylyl cyclase, and *PKA-R1* is defective in PKA.

More recently a reverse genetic approach has been used to explore memory storage in *Drosophila*. Various transgenes (see [Chapter 3](#)) are placed under the control of an inducible promoter that is heat-sensitive, so that by heating and cooling the fly a particular gene can be turned on or off. This inducible control over gene expression, which we shall return to again later in the chapter, is useful for studying synaptic or behavioral plasticity in adult animals. It minimizes any potential effect that a transgene might produce on the development of the brain and therefore allows one to read out the selective effect of the gene on adult behavior.

The first such experiment involved inducing the expression of transgenes that blocked the catalytic subunit of PKA. William Quinn and his colleagues found that blocking the action of PKA, even transiently, interferes with the fly's ability to learn and to form short-term memory. A similar disruption of learning and memory was observed in a mutant of a *Drosophila* homolog of the PKA catalytic subunit. These experiments indicate the importance of the cAMP signal transduction pathway is critical for associative learning and short-term memory in *Drosophila*.

Long-term memory after repeated training in *Drosophila* also requires new protein synthesis. *Drosophila* expresses

both a CREB activator and a CREB-2 repressor. Jerry Yin, Tim Tully, and their colleagues found that overexpression of the repressor (CREB-2), which presumably prevents the expression of cAMP-activated genes, selectively blocks long-term memory without interfering with learning or short-term memory. Conversely, overexpression of the CREB activator results in immediate long-term memory, even with a training procedure that produces only short-term memory in wild-type flies.

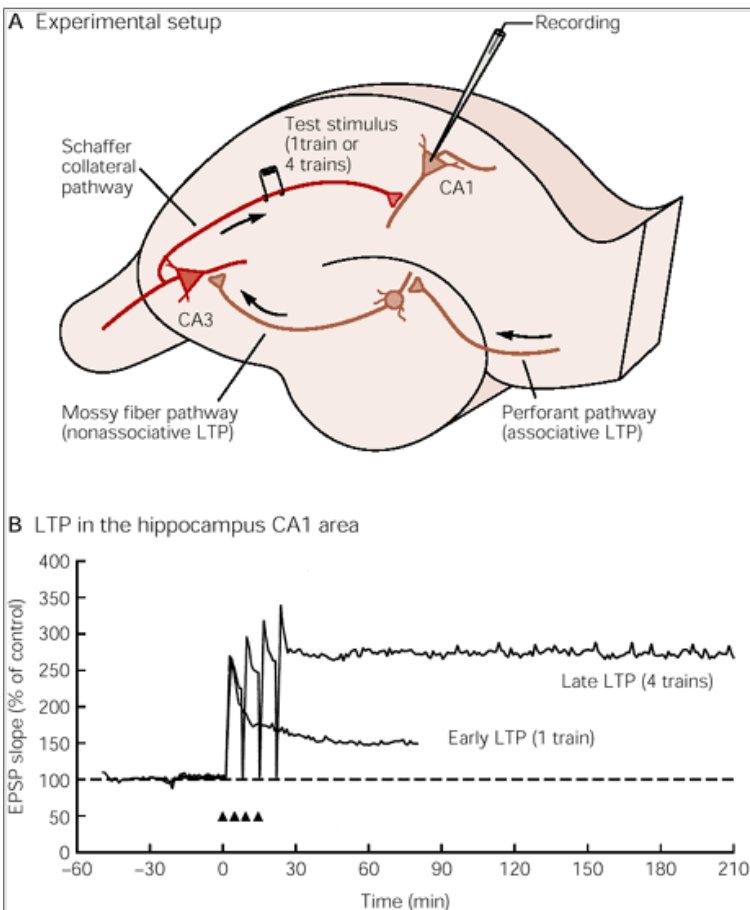

Figure 63-9 Long-term potentiation (LTP) in the Schaffer collateral pathway to the CA1 region of the hippocampus.

A. Experimental setup for studying LTP in the CA1 region of the hippocampus. The Schaffer collateral pathway is stimulated electrically and the response of the population of pyramidal neurons is recorded.

B. Comparison of early and late LTP in a cell in the CA1 region of the hippocampus. The graph is a plot of the slope (rate of rise) of the excitatory postsynaptic potentials (EPSP) in the cell as a function of time. The slope is a measure of synaptic efficacy. Excitatory postsynaptic potentials were recorded from outside the cell. A test stimulus was given every 60 s to the Schaffer collaterals. To elicit early LTP a single train of stimuli is given for 1 s at 100 Hz. To elicit the late phase of LTP four trains are given separated by 10 min. The resulting early LTP lasts 2-3 hours, whereas the late LTP lasts 24 or more hours.

Explicit Memory in Mammals Involves Long-Term Potentiation in the Hippocampus

What mechanisms are used to store explicit memory—information about people, places, and objects? One important component of the medial temporal system of higher vertebrates involved in the storage of explicit memory is the hippocampus ([Chapter 62](#)). As first shown by Per Andersen, the hippocampus has three major pathways: (1) the *perforant pathway*, which projects from the entorhinal cortex to the granule cells of the dentate gyrus; (2) the *mossy fiber pathway*, which contains the axons of the granule cells and runs to the pyramidal cells in the CA3 region of the hippocampus; and (3) the *Schaffer collateral pathway*, which consists of the excitatory collaterals of the pyramidal cells in the CA3 region and ends on the pyramidal cells in the CA1 region ([Figure 63-7](#)).

In 1973 Timothy Bliss and Terje Lom[•] discovered that each of these pathways is remarkably sensitive to the history of previous activity. A brief high-frequency train of stimuli (a tetanus) to any of the three major synaptic pathways increases the amplitude of the excitatory postsynaptic potentials in the target hippocampal neurons. This facilitation is called *long-term potentiation* (LTP). The mechanisms underlying LTP are not the same in all three pathways. LTP can be studied in the intact animal, where it can last for days and even weeks. It can also be examined in slices of hippocampus and in cell culture for several hours. We shall first consider the mossy fiber pathway.

P.1260

Long-Term Potentiation in the Mossy Fiber Pathway Is Nonassociative

The mossy fiber pathway consists of the axons of the granule cells of the dentate gyrus. The mossy fiber terminals release glutamate as a transmitter, which binds to both NMDA and non-NMDA receptors on the target pyramidal cells. However, in this pathway the NMDA receptors have only a minor role in synaptic plasticity under most conditions; blocking the NMDA receptors has no effect on LTP. Similarly, blocking Ca^{2+} influx into the postsynaptic pyramidal cells in the CA3 region does not affect LTP ([Figure 63-8](#)).

Instead, LTP in the mossy fiber pathway region has been found to depend on Ca^{2+} influx into the *presynaptic* cell after the tetanus. The Ca^{2+} influx appears to activate Ca^{2+} /calmodulin-dependent adenylyl cyclase thereby increasing the level of cAMP and activating PKA in the presynaptic neuron, just as in the sensory neurons of *Aplysia* during associative learning. Moreover, mossy fiber LTP can be regulated by a modulatory input. This input is noradrenergic and engages β -adrenergic receptors, which activate adenylyl cyclase, as does the serotonergic input in *Aplysia*.

Long-Term Potentiation in the Schaffer Collateral and Perforant Pathways Is Associative

The Schaffer collateral pathway connects the pyramidal cells of the CA3 region of the hippocampus with those of the CA1 region ([Chapter 5](#) and [Figures 63-7](#) and [63-9A](#)). Like the mossy fiber terminals, the terminals of the Schaffer collaterals also use glutamate as transmitter, but LTP in the Schaffer collateral pathway requires activation of the NMDA-type of glutamate receptor ([Figures 63-9B](#) and [63-10](#)). Therefore, LTP in CA1 cells has two characteristic features that distinguish it from LTP in the mossy fiber pathway, both of which derive from the known properties of the NMDA receptor.

First, LTP in the Schaffer collateral pathway typically requires activation of several afferent axons together, a feature called *cooperativity*. This feature derives from the fact that the NMDA receptor-channel becomes functional and conducts Ca^{2+} only when two conditions are met: Glutamate must bind to the postsynaptic NMDA receptor *and* the membrane potential of the postsynaptic cell must be sufficiently depolarized by the cooperative firing of several afferent axons to expel Mg^{2+} from the

mouth of the channel (Figure 63-10). Only when Mg^{2+} is expelled can Ca^{2+} influx into the postsynaptic cell occur. Calcium influx initiates the persistent enhancement of synaptic transmission by activating two calcium-dependent serine-threonine protein kinases—the Ca^{2+} /calmodulin-dependent protein kinase and protein kinase C—as well as PKA and the tyrosine protein kinase fyn.

Second, LTP in the Schaffer collateral pathway requires concomitant activity in both the presynaptic and postsynaptic cells to adequately depolarize the post-synaptic cell, a feature called *associativity*. As we have seen, to initiate the Ca^{2+} influx into the postsynaptic cell, a strong presynaptic input sufficient to fire the postsynaptic cell is required.

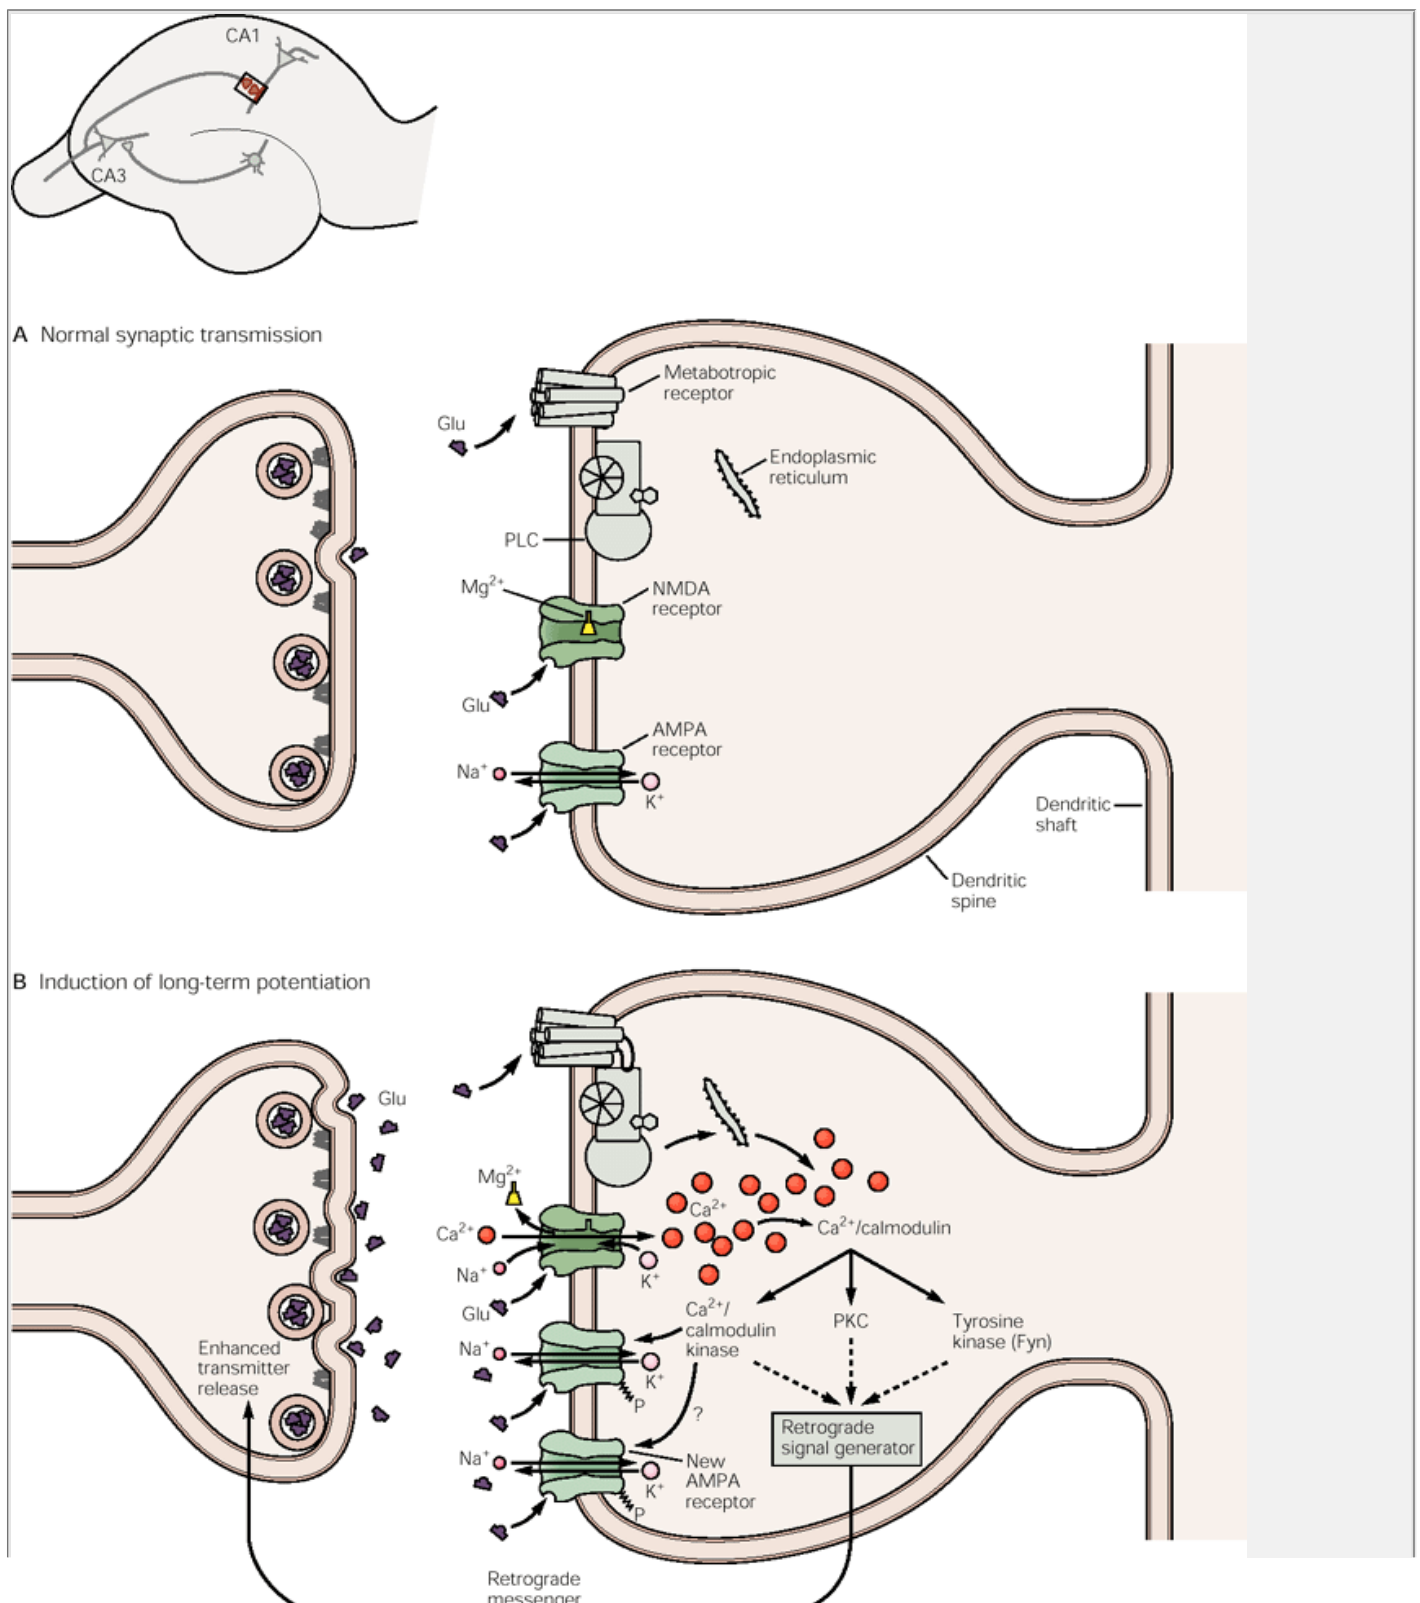

The finding that LTP in the Schaffer collateral pathway requires simultaneous firing in both the postsynaptic and presynaptic neurons provides direct evidence for *Hebb's rule*, proposed in 1949 by the psychologist Donald Hebb: "When an axon of cell A... excites cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A's efficiency as one of the cells firing B is increased." As discussed in Chapter 56, a similar principle is involved in fine-tuning synaptic connections during the late stages of development.

The induction of LTP in the CA1 region of the hippocampus depends on four postsynaptic factors: postsynaptic depolarization, activation of NMDA receptors, influx of Ca^{2+} , and activation by Ca^{2+} of several second-messenger systems in the postsynaptic cell. The mechanisms for the expression of this LTP, on the other hand, is still uncertain. It is thought to involve not only

P.1261

P.1262

an increase in the sensitivity and number of the postsynaptic non-NMDA (AMPA) receptors to glutamate as a result of being phosphorylated by the Ca^{2+} /calmodulin-dependent protein kinase, but also an increase in transmitter release from the presynaptic terminals of the CA3 neuron (Figure 63-11). Evidence for enhanced presynaptic function is based on two observations. First, biochemical studies suggest that the release of glutamate is enhanced during LTP. Second, as we shall see later, quantal analysis indicates that the probability of transmitter release increases greatly during LTP.

Figure 63-10 (Opposite) A model for the induction of the early phase of long-term potentiation. According to this model NMDA and non-NMDA receptor-channels are located near each other in dendritic spines.

- A.** During normal, low-frequency synaptic transmission glutamate (**Glu**) is released from the presynaptic terminal and acts on both the NMDA and non-NMDA receptors. The non-NMDA receptors here are the AMPA type. Na^+ and K^+ flow through the non-NMDA channels but not through the NMDA channels, owing to Mg^{2+} blockage of this channel at the resting level of membrane potential.
- B.** When the postsynaptic membrane is depolarized by the actions of the non-NMDA receptor-channels, as occurs during a high-frequency tetanus that induces LTP, the depolarization relieves the Mg^{2+} blockage of the NMDA channel. This allows Ca^{2+} to flow through the NMDA channel. The resulting rise in Ca^{2+} in the dendritic spine triggers calcium-dependent kinases (Ca^{2+} /calmodulin kinase and protein kinase C) and the tyrosine kinase Fyn that together induce LTP. The Ca^{2+} /calmodulin kinase phosphorylates non-NMDA receptor-channels and increases their sensitivity to glutamate thereby also activating some otherwise silent receptor channels. These changes give rise to a postsynaptic contribution for the maintenance of LTP. In addition, once LTP is induced, the postsynaptic cell is thought to release (in ways that are still not understood) a set of retrograde messengers, one of which is thought to be nitric oxide, that act on protein kinases in the presynaptic terminal to initiate an enhancement of transmitter release that contributes to LTP.

Figure 63-11 Maintenance of the early phase of LTP in the CA1 region of the hippocampus depends on an increase in presynaptic transmitter release. Quantal analysis of LTP in area CA1 is based on a coefficient of variation of evoked responses. This analysis assumes that the number of quanta of transmitter released follows a binomial distribution, where the coefficient of variation (mean squared/variance) provides an index of transmitter release from the presynaptic terminal that is independent of quantal size. (From [Malinow and Tsien 1990](#).)

- A.** With LTP the ratio of mean squared to variance increases, indicating an increase in transmitter release. This increase occurs only in the pathway that is paired with depolarization of the postsynaptic cell. It does not occur in a control pathway that is not paired.
- B.** At normal rates of stimulation the number of failures in transmission is significant (60%). After LTP the percentage of failures decreases to 20%, another indication that LTP is presynaptic.

Since induction of LTP requires events only in the postsynaptic cell (Ca^{2+} influx through NMDA channels), whereas expression of LTP is due in part to a subsequent event in the presynaptic cells (increase in transmitter release), the presynaptic cells must somehow receive information that LTP has been induced. There is now evidence that calcium-activated second messengers, or perhaps Ca^{2+} itself, causes the postsynaptic cell to release one or more retrograde messengers from its active dendritic spines. Recent pharmacological and genetic experiments have identified nitric oxide (NO), a gas that diffuses readily from cell to cell, as one of the possible candidate retrograde messengers involved in LTP.

These studies of the Schaffer collateral pathway indicate that LTP in CA1 uses two associative mechanisms in series: a Hebbian mechanism (simultaneous firing in both the pre- and postsynaptic cells) and activity-dependent presynaptic facilitation. A similar set of mechanisms is responsible for LTP in the perforant pathway. As we saw earlier, two associative mechanisms in series also contribute to classical conditioning in *Aplysia*.

Long-Term Potentiation Has a Transient Early and a Consolidated Late Phase

As with memory storage ([Chapter 62](#)), LTP has phases. One stimulus train produces an early, short-term phase of LTP (called *early LTP*) lasting 1-3 hours; this component does not require new protein synthesis. Four or more trains induce a more persistent phase of LTP (called *late LTP*) that lasts for at least 24 hours and requires new protein and RNA synthesis. As we have seen, the mechanisms for the early, short-term phase are quite different in the Schaffer collateral and mossy fiber

pathways. However, the mechanisms for the late, long-term phase in the two pathways appear similar. In both pathways late-phase LTP requires the synthesis of new mRNA and protein and recruits the cAMP-PKA-MAPK-CREB signaling pathway.

What are the properties of this late phase of LTP? Does long-term explicit memory storage, like implicit
P.1263

P.1264

memory storage, also require the growth of new synaptic connections? In fact, cellular-physiological studies are beginning to suggest that the late phase of LTP involves the activation, perhaps the growth, of additional presynaptic machinery for transmitter release and the insertion of new clusters of postsynaptic receptors.

Figure 63-12 The early and late phases of LTP are evident in the synaptic transmission between a single CA3 cell and a single CA1 cell. (From Bolshakov et al. 1997.)

A. A single CA3 cell can be stimulated selectively to produce a single elementary synaptic potential in a CA1 cell. When the CA3 cell is stimulated repeatedly at low frequency, it gives rise to either an elementary response of the size of a miniature synaptic potential or a failure.

B. In control cells there are many failures; the synapse has a low probability of releasing vesicles. The distribution of the amplitudes of many responses can be approximated by two Gaussian curves, one centered on zero (the failures) and the other centered on 4 pA (the successful responses). These histograms are consistent with the type of synapse illustrated here, in which a single CA3 cell makes a single connection on a CA1 cell. This connection has a single active zone from which it releases a single vesicle in an all-or-none manner (failures or successes).

C. With the early phase of LTP the probability of release rises significantly, but the two Gaussian curves in the distribution of responses is consistent with the view that a single release site still releases only a vesicle but now with a high probability of release.

D. When the late phase of LTP is induced by a cAMP analog (**Sp-cAMPS**), the distribution of responses no longer fits two Gaussian curves but instead requires three or four Gaussian curves, suggesting the possibility that new presynaptic active zones and postsynaptic receptors have grown. These effects are blocked by anisomycin, an inhibitor of protein synthesis.

Charles Stevens and his colleagues and Steven Siegelbaum and Vadim Bolshakov have now examined LTP by stimulating a *single* presynaptic CA3 neuron and recording from a *single* CA1 postsynaptic cell. When the CA3 neuron is stimulated repeatedly at a low rate, most of the time the CA1 cell fails to respond with a synaptic potential. Only on occasion does activity in the presynaptic neuron lead to a small response, about 4 pA in amplitude, in the postsynaptic cell (Figure 63-12A). This response is approximately the size of a single spontaneous miniature synaptic potential (Chapter 14). When many failures and unitary responses are collected and measured, the failures of release and the unitary responses can be described by two random (Gaussian) distributions, one centered at zero, corresponding to the failures of release, and the other centered around 4 pA, corresponding both to successful responses and to the size of spontaneously released miniature synaptic potentials (Figure 63-12B). These distributions lend themselves to a surprisingly clear anatomical explanation. They suggest that a single CA3 neuron makes only a single functional synaptic contact on a CA1 neuron. This single synaptic contact appears to have only one active zone from which the transmitter content of only a single vesicle is released, in an all-or-none way, by a presynaptic action potential. In the basal state (where there are many more failures than responses) the probability of release of the vesicle is low. Thus, this situation is not very different from other central synaptic connections where a single release site typically releases only a single vesicle in an all-or-none fashion (Chapter 15).

What happens during the early phase of LTP? In the early phase the number of failures decreases and the number of successes increases, but the amplitude histograms of the responses and failures are still fit by two Gaussian distributions (corresponding to failures of release and successful responses). This indicates that the early phase of LTP produces no change in the number of synapses, the number of active zones, or the maximal number of vesicles released with each action potential (Figure 63-12C). Thus the early phase of LTP represents a functional change—an increase in the *probability* of transmitter release—without structural changes. An action potential still releases only one vesicle of transmitter from a single release site, but now it does so more reliably.

An equivalent of the late-phase LTP can be induced chemically, by exposing the neurons to permeant cAMP. After the late phase of LTP begins the distribution of successful responses changes dramatically and can no longer be approximated by two Gaussian functions. The responses now are not simply zero and 4 pA but are 8, 12, and even 20 pA in amplitude, so that several Gaussian curves are required to describe the distribution of responses (Figure 63-12D). This change suggests that during the late phase of LTP a single action potential in a single CA3 cell releases several vesicles of transmitter onto the CA1 neuron. Since each release site is thought to release only one vesicle in an all-or-none fashion, such an increase in the number of vesicles released would seem to entail growth of new pre-synaptic release sites as well as new clusters of post-synaptic receptors. Consistent with this idea, and with the properties of the late phase of LTP, the generation of these new distributions requires new protein synthesis (Figure 63-13).

Genetic Interference With Long-Term Potentiation Is Reflected in the Properties of Place Cells in the Hippocampus

LTP is an artificially induced change in synaptic strength produced by electrical stimulation of synaptic pathways. Does this form of synaptic plasticity exist naturally? If so, how does it affect the normal processing of information for memory storage in the hippocampus?

In 1971 John O'Keefe and John Dostrovsky made the remarkable discovery that the hippocampus contains a cognitive map of the spatial environment in which an animal moves. The location of an animal in a particular space is encoded in the firing pattern of individual pyramidal cells, the very cells that undergo LTP when their afferent pathways are stimulated electrically.

A mouse's hippocampus has about a million pyramidal cells. Each of these cells is potentially a *place cell*, encoding a position in space. When an animal moves around, different place cells in the hippocampus fire. For example, one cell will fire only when the animal's head enters a particular area in the north end of the space, while other cells will fire when the animal takes other positions at the south end of that space (Figure 63-14A,63-14B). Thus, the mouse's whereabouts are signaled by the discharge of a unique population of hippocampal place cells.

By this means the animal is thought to form a "place field," an internal representation of the space that it occupies. When the animal enters a new environment, new place fields are formed within minutes and are stable

P.1265

P.1266

for weeks to months. The same pyramidal cells may signal different information in different environments and can therefore be used in more than one spatial map.

Figure 63-13 A model for the early and late phase of LTP. A single train of action potentials leads to early LTP by activating NMDA receptors, Ca^{2+} influx into the postsynaptic cell, and a set of second messengers. With repeated trains the Ca^{2+} influx also recruits an adenylyl cyclase, which activates the cAMP-dependent protein kinase (cAMP kinase) leading to its translocation to the nucleus, where it phosphorylates the CREB protein. CREB in turn activates targets that are thought to lead to structural changes. Mutations in mice that block PKA or CREB reduce or eliminate the late phase of LTP. The adenylyl cyclase can also be modulated by dopaminergic and perhaps other modulatory inputs. **BDNF** = brain-derived neurotrophic factor; **C/EBP β** = transcription factor; **P** = phosphate; **R(AB)** dominant negative PKA; **tPA** tissue plasminogen activator.

Figure 63-14A The firing patterns of pyramidal cells in the hippocampus create an internal representation of the animal's location within its surrounding. A mouse is attached to a recording cable and placed inside a cylinder (49 cm in diameter by 34 cm high). The other end of the cable goes to a 25-channel commutator attached to a computer-based spike-discrimination system. The cable is also used to supply power to a light-emitting diode mounted on the headstage the mouse carries. The entire apparatus is viewed with an overhead TV camera whose output goes to a tracking device that detects the position of the mouse. The output of the tracker is sent to the same computer used to detect spikes, so that parallel time series of positions and spikes are recorded. The occurrence of spikes as a function of position is extracted from the basic data and is used to form two-dimensional firing-rate patterns that can be numerically analyzed or visualized as color-coded firing-rate maps. (Based on [Muller et al. 1987.](#))

The rapid formation of place fields and their persistence for weeks offer an excellent opportunity to ask, How are place fields formed and maintained? Is LTP important for the formation or maintenance of place fields? To address these questions two types of mutations have been examined in mice, each of which interferes with LTP in a different way.

One mutation was produced by Joe Tsien, Susumu Tonegawa, and their colleagues by selectively knocking out NMDA R1, one of the subunits of the NMDA receptor, in the pyramidal cells of the CA1 region. This restricted knockout, limited to just the CA1 region, disrupts LTP in the Schaffer collateral pathway completely ([Box 63-1](#)).

In the other mutation, produced by Mark Mayford and his colleagues, a persistently active form of the Ca²⁺/calmodulin-dependent kinase is expressed throughout the hippocampus. This mutated gene product does not affect LTP produced at 100 Hz stimulation, the frequency commonly used in the laboratory, but it does interfere with LTP produced at low frequencies of stimulation, in the range of 1-10 Hz ([Box 63-1](#)). These lower frequencies are interesting because they are in the physiological range of a prominent spontaneous rhythm in the hippocampus, called the *theta rhythm*, that occurs in an animal as it moves in the environment.

In both types of mutants the interference with LTP does not prevent the formation of place fields. Although the place fields formed in the absence of LTP are larger and fuzzier in outline than normal, LTP is not required for the basic transformation of sensory information into

place fields. LTP is required for fine-tuning the properties of place cells and ensuring their stability over time.

Figure 63-14B The firing-rate patterns from four successive recording sessions in a single cell from a wild-type mouse and a mouse carrying a gene for a persistently active Ca²⁺/calmodulin-dependent kinase. Before each recording session the animal was taken out of the cylinder and reintroduced into it. In each of the four sessions the positional firing pattern for the wild-type cell is stable. By contrast, the pattern of the mutant cell is unstable in sessions 2 and 3.

For example, pyramidal cells that encode for overlapping positions in space fire synchronously when the animal enters the space represented by those cells. Thomas McHugh and his colleagues found that this correlated firing is lost in mice lacking a functional NMDA receptor in the CA1 region. Alex Rotenberg found that the defect is more severe in mice that overexpress an activated form of the Ca²⁺/calmodulin-dependent protein kinase. As noted earlier, in wild-type mice a place field forms within minutes after an animal enters a new environment and, once formed, remains stable in that environment for months. In contrast, when mutant mice are removed from a space and then put back into the same space, cells that were previously active in that space form *different* place fields. This instability of place cells is reminiscent of the memory defect in H.M. and other patients with lesions of the medial temporal lobe. Each time these patients enter the same space, they act as if they have never seen it before.

Associative Long-Term Potentiation Is Important for Spatial Memory

If LTP is a synaptic mechanism for maintaining a coherent spatial map over time, then defects in LTP should interfere with spatial memory. One spatial memory test is a water maze in which a mouse must find a platform hidden under opaque water in a pool. When released at random locations around the pool, the mouse must use contextual (spatial) cues—markings on the walls of the room in which the pool is located—to find the platform. This task requires the hippocampus. In a simple noncontextual

P.1268

P.1269

P.1270

P.1271

P.1272

(nonspatial) version of this test the platform is raised above the surface of the water or marked with a flag so that it is visible, permitting the mouse to navigate to the platform directly. This task does not require the hippocampus.

Box 63-1 Restricting Gene Knockout and Regulating Transgene Expression

Biological analysis of learning requires the establishment of a causal relation between specific molecules and learning. This relationship, which has been difficult to demonstrate in mammals, can now be studied in mice either by the use of transgenes or the selective knockout of genes. With *transgenes* a new gene is introduced into the brain under the control of a promoter that expresses that gene in a specific region of the brain. With *gene knockout* specific gene deletions are induced in embryonic stem cells through homologous recombination (see [Figure 3-8](#)).

Experiments using transgenes and gene knockout have made it possible to examine the roles of NMDA receptors and different second-messenger kinases in a variety of learning mechanisms in the hippocampus, including long-term potentiation, spatial learning, and the development and maintenance of a cognitive map of space.

With conventional gene knockout techniques animals inherit the genetic deletions in all of their cell types. Global genetic deletion may cause developmental defects that interfere with the later functioning of neural circuits important for memory storage. As a result, interpretation of the results from conventional knockout mice runs into two types of difficulties. First, it is often difficult to exclude the possibility that the abnormal phenotype observed in mature animals results directly or indirectly from a developmental defect. Second, global gene knockout makes it difficult to attribute abnormal phenotypes to a particular type of cell within the brain.

To improve the utility of gene knockout and transgene technology, methods have been developed to restrict gene expression locally or temporally. One method for restricting gene knockout locally exploits the *Cre/loxP* system, a site-specific recombination system, derived from the P1 phage, in which the Cre recombinase catalyzes recombination between 34 bp *loxP* recognition sequences ([Figure 63-15](#)). The *loxP* sequences can be inserted into the genome of embryonic stem cells by homologous recombination such that they flank one or more exons of the gene one is interested in. Thus the gene encoding the R1 subunit of the NMDA receptor can be floxed and then ablated selectively in the CA1 region of the hippocampus. Loss of the R1 subunit leads to loss of LTP. Moreover, mice that lack this gene only in the CA1 region of the hippocampus show a deficiency in spatial memory ([Figure 63-17](#)). In contrast, these mice show no deficit in tasks that do not involve the hippocampus, such as learning simple visual discrimination.

In addition to regional restriction of gene expression, effective use of genetically modified mice requires control over the timing of gene expression. The ability to turn a transgene on and off gives the investigator an additional degree of flexibility and can exclude the possibility that any abnormality observed in the phenotype of the mature animal is the result of a developmental defect produced by the transgene. This can be done in mice by constructing a gene that can be turned on or off by giving a drug.

One starts by creating two lines of mice ([Figure 63-16](#)). One line carries a particular transgene, for example CaMKII-Asp 286, a mutated form of the gene CaMK-II coding for a constitutively active kinase (line 1). Instead of being attached to its normal promoter, the transgene is attached to the promoter *tet-O* that is ordinarily found only in bacteria. This promoter cannot, by itself, turn on the gene; it needs to be activated by a specific transcriptional regulator. Thus, a second transgene expressed in the second line of mice encodes a hybrid transcriptional regulator called *tetracycline transactivator* (tTA) that recognizes and binds to the *tet-O* promoter (line 2). Expression of tTA is placed under the control of a region-specific promoter, such as the promoter for CaMKII.

When the two lines of mice are mated some of the offspring will carry both transgenes. In these mice the tTA binds to the *tet-O* promoter and activates the mutated *CaMKII* gene. This mutant causes abnormalities in long-term potentiation. But when the animal is given doxycycline, the drug binds to the transcription factor tTA causing it to undergo a change in shape that makes it come off the promoter ([Figure 63-16](#)). The cell stops expressing *CaMKII* and long-term potentiation returns to normal, demonstrating that the transgene acts on the adult synapse and does not interfere with the development of the synapse.

One can also generate mice that express a mutant form of tTA called reverse tTA (rtTA). This transactivator will *not* bind to *tet-O* unless the animal is fed doxycycline. In this case the transgene is always turned off unless the drug is given.

A Regional restriction of gene expression

B Action of *CaMKII-Cre* recombinase is restricted to CA1 region

Figure 63-15 (Opposite) Using the *Cre/loxP* system to restrict the region of gene knockout.

A. A mouse homozygous for the floxed R1 subunit of the NMDA receptor (**line 1**) is generated from embryonic stem cells by conventional techniques and is crossed to a second mouse that contains a *Cre* transgene under the control of a transcriptional promoter from the *CaMKII* gene (**line 2**). In progeny that are homozygous for the floxed gene and that carry the *Cre* transgene, the floxed gene will be deleted by *Cre/loxP* recombination but only in those cell types in which the *Cre* gene-associated promoter is active. By this means efficient gene knockout is accomplished in postmitotic neurons in a highly restricted manner, limited to the CA1 pyramidal cells of the hippocampus.

B. LacZ staining reveals the region where recombination was successful and led to the removal of a floxed stopper sequence that allows LacZ to be expressed. When the *Cre* recombinase is combined with the promoter for the Ca^{2+} /calmodulin-dependent kinase, the transgene is restricted to the CA1 region. This is evident in the section of the brain illustrated here. (From [Tsien et al. 1996a.](#))

Temporal restriction of gene expression

Figure 63-16 Using the tetracycline system to control the timing of gene expression. Two independent lines of transgenic mice are mated so that two transgenes are introduced into a single mouse. In the tetracycline system a bacterial transcription factor, the tetracycline transactivator (tTA), recognizes a bacterial promoter (the *tetO* promoter). When the transactivator binds to the promoter it activates its downstream gene, in this case a constitutively active form of CaMKII, *CaMKII-Asp286*. When the animal is given doxycycline the drug binds to the transcription factor, tTA, producing a conformational change in tTA that causes it to come off the promoter. (From [Mayford et al. 1996](#))

A LTP defect in the Schaffer collateral pathway

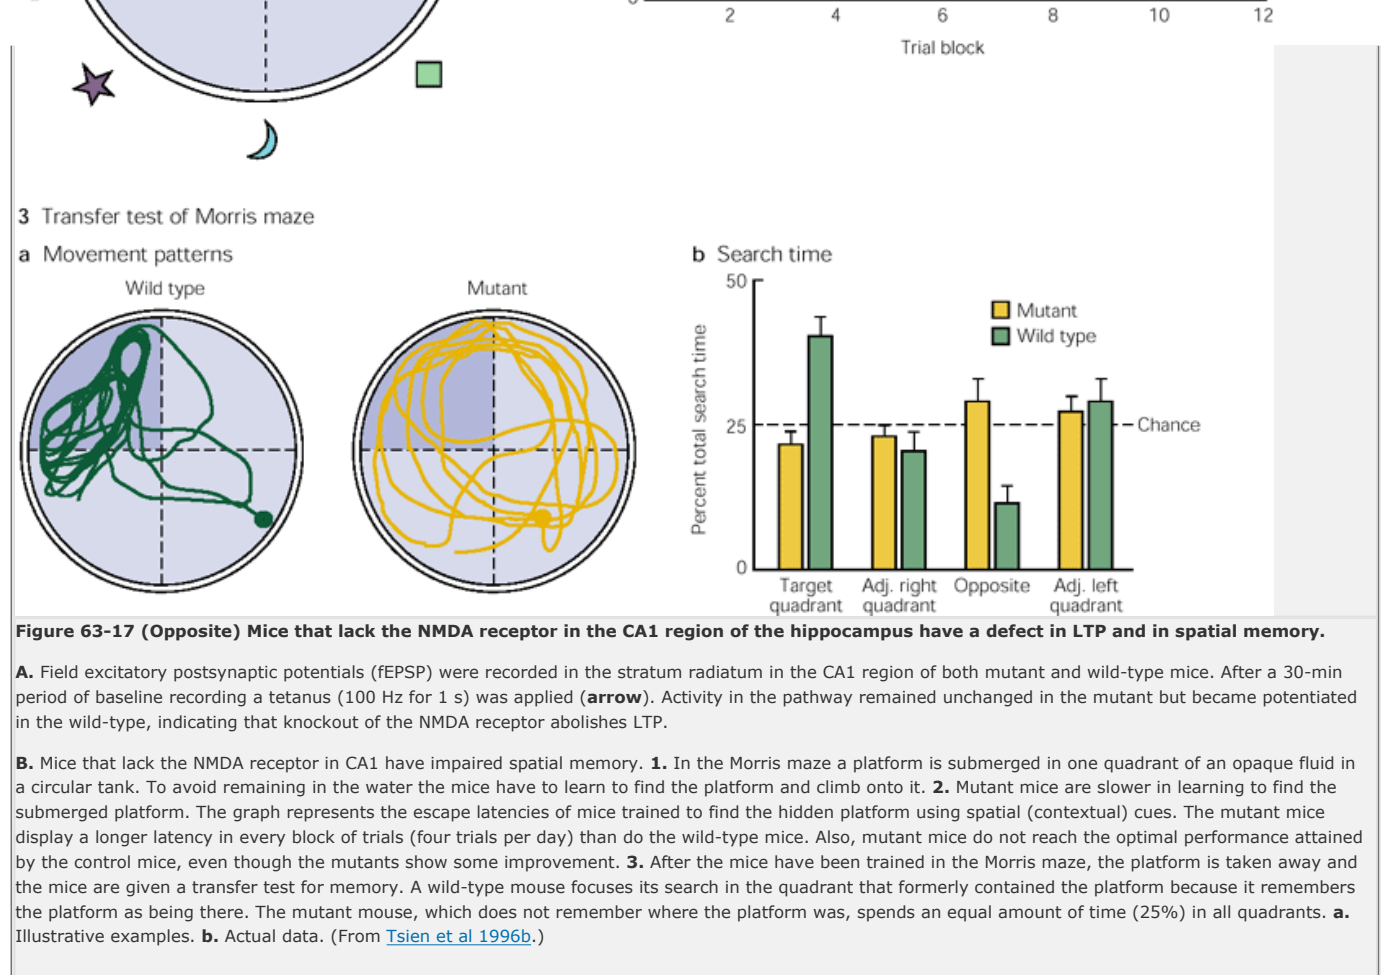

B Spatial memory defects

1 The Morris maze

2 Escape latencies

Richard Morris demonstrated that when NMDA receptors are blocked by the injection of a pharmacological antagonist into the hippocampus, the animal can navigate to the visible platform in the noncontextual version of the water maze test but cannot find its way to the submerged platform in the contextual version. These experiments suggested that some mechanism involving NMDA receptors in the hippocampus, perhaps LTP, is involved in spatial learning. More direct evidence for this correlation has come from genetic experiments with the two types of mutant mice described in Box 63-1.

In the first type of mutant the R1 subunit of the NMDA receptor of the pyramidal cells of the CA1 region is selectively knocked out. As a result, basal transmission is normal but LTP is completely disrupted (Figure 63-17A). Although this disruption is restricted to the Schaffer collateral pathway, these mice nevertheless have a serious deficit in spatial memory when tested in the water maze (Figure 63-17B and C). These findings provide the most compelling evidence so far that the NMDA channels and NMDA-mediated synaptic plasticity in the Schaffer collateral pathway are important for spatial memory.

In the second type of mutant, expression of the persistently active form of the Ca^{2+} /calmodulin-dependent protein kinase can be turned on and off at will. Expression of the kinase selectively interferes with LTP when the frequency of electrical stimulation is between 1 and 10 Hz, and this results in an instability in the hippocampal place cells (Figure 63-18). These mutant mice also do not remember spatial tasks. But when the transgene is turned off, the LTP becomes normal and the animal's capability for spatial memory is restored!

These two sets of experiments based on the restricted knockout of the NMDA receptor and the regulated expression of the Ca^{2+} /calmodulin-dependent kinase make it clear that LTP in the Schaffer collateral pathway is important for spatial memory.

How are defects in the various phases of LTP reflected in defects in the phase of memory storage? Indeed, the memory deficits are surprisingly selective. Selective expression in the hippocampus of the transgene that blocks cAMP-dependent protein kinase selectively disrupts the late phase of LTP in the Schaffer collateral pathway. Animals with this deficit have normal learning abilities and normal short-term memory when tested at one hour, but they cannot convert short-term memory into stable long-term memory. They have defective long-term memory when tested at 24 hours after training. Essentially similar results are obtained in mice that have a knockout of several isoforms of CREB-1, as well as in normal wild-type mice that are exposed to pharmacological inhibitors of protein synthesis or camp-dependent protein kinase. These animals learn well and have normal short-term memory but poor long-term memory.

Thus, interference with the early and late component of LTP in the Schaffer collateral pathway interferes with both short- and long-term memory, whereas selective interference with the late component of LTP interferes only with the consolidation of long-term memory. Together, these experiments provide insight into the genetic chain of causation that connects molecules to LTP, LTP to place cells, and place cells to the outward behavior of the animal as reflected in both short- and long-term spatial memory.

Is There a Molecular Alphabet for Learning?

The changes in synaptic efficacy that we have encountered in studies of both implicit and explicit forms of storage raise three key issues in a neurobiological approach to learning.

First, the finding that the molecular mechanisms of some associative forms of synaptic plasticity are based on those of nonassociative forms in the same cell suggests that there may be a molecular alphabet for synaptic plasticity—simpler forms of plasticity might represent elements of more complex forms. Of course, all of these synaptic mechanisms are embedded in distributed neural circuits with considerable additional computational power, which can thus add substantial complexity to the actions of individual cells.

Second, the molecular mechanisms of elementary forms of associative memory storage used in both implicit and explicit learning are similar. In the two processes we have considered—activity-dependent presynaptic facilitation for storing implicit memory and associative LTP for storing explicit memory—the plasticity of neuronal function seems to derive from the associative properties of specific proteins: from the ability of proteins, such as adenylyl cyclase and the NMDA receptor, to respond conjointly to two independent signals.

Finally, despite clear differences in behavioral logic in the neural systems recruited for the task, implicit and explicit memory storage seem to use elements of a

common genetic switch, involving cAMP-dependent protein kinase, MAP kinase, and CREB, to convert labile short-term memory into long-term memory.

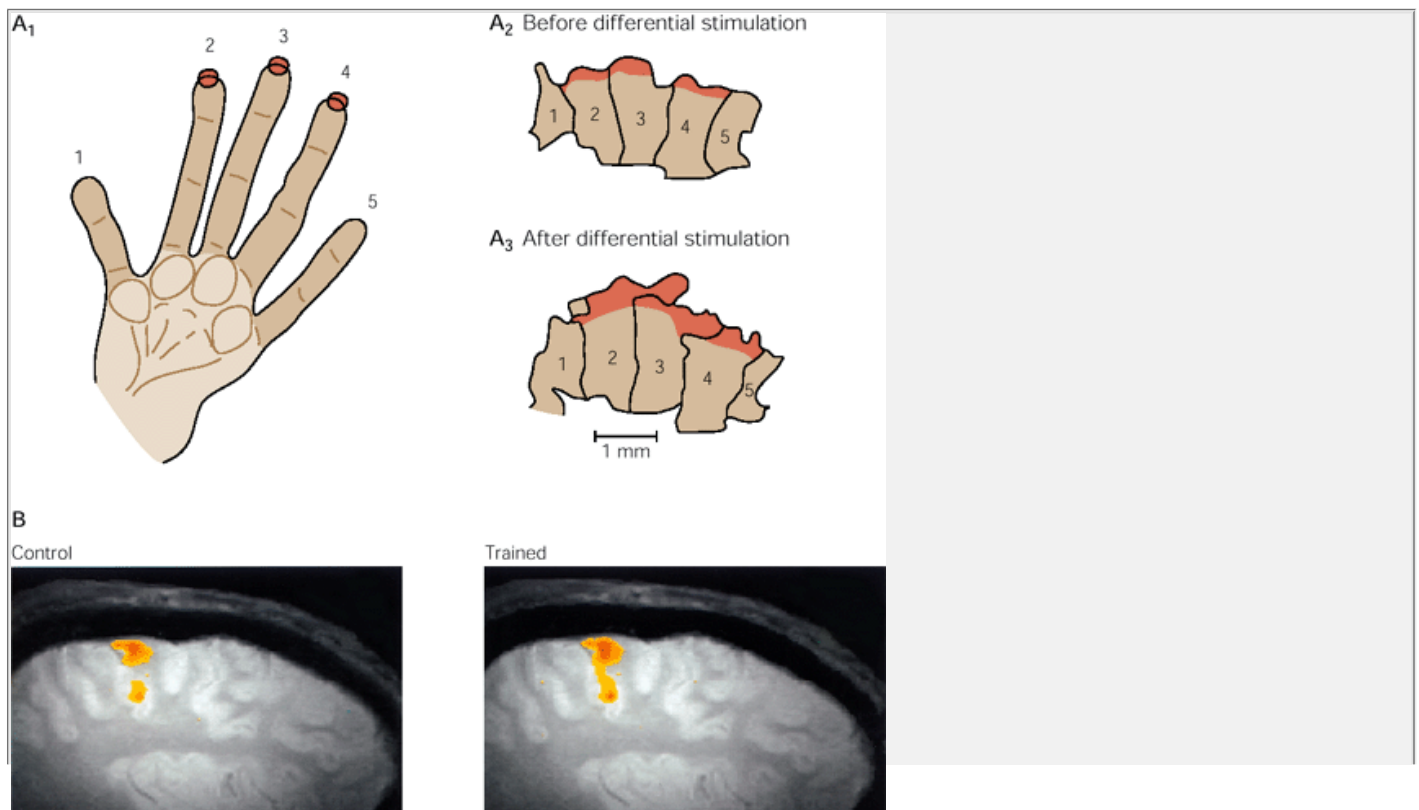

Figure 63-18 Reversal of the deficit in LTP and in spatial memory in the CA1 region of the hippocampus.

A. Field excitatory postsynaptic potentials (fEPSP) slopes before and after tetanic stimulation were recorded and expressed as the percentage of pretetanus baseline. Stimulation at 10 Hz (arrow) for 1.5 min induced a transient depression in activity followed by potentiation in wild-type mice but only a slight depression and no potentiation in transgenic mice. Doxycycline treatment (Dox) reversed the defect in the transgenic mice so that they show potentiation compared with wild type.

B. The Barnes maze measures the same spatial memory system explored in the Morris water maze. This maze consists of a platform with 40 holes, only one of which (marked in black) leads to an escape tunnel that allows the mouse to exit the platform. The mouse is placed in the center of the platform. Because mice do not like open, well-lit spaces, they try to escape from the platform. The only way they can do that is to find the one hole that leads to the escape tunnel. The most efficient way of doing that (and the only way of meeting the criteria set for the task by the experimenter) is to use the distinctive markings on the four walls.

C. Percentage of transgenic and wild-type mice that met the learning criterion on the Barnes circular maze. Three groups of mice were tested: transgenics with and without doxycycline and wild-types. Transgenics that received doxycycline performed as well as wild-types, whereas those without the doxycycline did not learn the task.

Figure 63-19 Training expands the existing representation of the fingers in the cortex.

A. A monkey was trained for 1 hour per day to perform a task that required repeated use of the tips of fingers 2, 3, and occasionally 4. After a period of repeated stimulation the portion of area 3b representing the tips of the stimulated fingers was substantially greater (**3**) than in untrained monkeys (**2**) measured 3 months before training). (Adapted from [Jenkins et al. 1990.](#))

B. A human subject trained to do a rapid sequence of finger movements will improve in accuracy and speed after three weeks of daily (10-20 min) training. In these MRI scans of local blood oxygenation level-dependent signals in the primary motor cortex, the region activated in trained subjects (after three weeks of training) is larger than the region activated in control subjects who performed unlearned finger movements in the same hand. The change in cortical representation with the learned motor sequence persisted for several months.

Changes in the Somatotopic Map Produced by Learning May Contribute to the Biological Expression of Individuality

Learning, we have seen, can lead to structural alterations in the brain. How common are these changes in determining the functional architecture of the mature brain? This question has been examined in the somatosensory cortex.

The four maps of the body surface in the primary somatic sensory cortex vary among individuals in a manner that reflects different usage of sensory pathways. The connections of afferent pathways in the cortex can expand or retract depending on activity (see [Chapter 20](#)). Reorganization of afferent inputs is also evident at lower levels in the brain, specifically at the level of the dorsal column nuclei, which contain the first synapses of the somatic sensory system. Therefore, organizational changes probably occur throughout the somatic afferent pathway as well. As we grow up each of us is exposed to different combinations of stimuli and develops motor skills in different ways. Thus all brains—even the brains of identical twins who share the

P.1275

same genes—are uniquely modified by experience. This distinctive modification of brain architecture, along with a unique genetic makeup, constitutes a biological basis for individuality.

The process by which experience alters the somatosensory maps in the cortex is illustrated in an experiment in which adult monkeys were trained to use only their middle three fingers to obtain food. After several thousand trials of this behavior the area of cortex devoted to the middle finger expanded greatly ([Figure 63-19](#)). Practice alone therefore may strengthen the effectiveness of existing patterns of connections.

Experiments such as this one suggest that early development of the input connections to cortical neurons in the somatic sensory system may depend on correlated activity in different afferent axons. As we have seen, cooperative activity in different afferent fibers stabilizes the development of ocular dominance columns in the visual system ([Chapter 56](#)). In turn, the use of correlated firing to fine-tune cortical connections may depend on mechanisms that require correlated firing similar to those of LTP. For example, when the skin of two adjacent fingers of a monkey were surgically connected to ensure that the connected fingers were always used together, the correlation of inputs from the joined fingers abolished the normally sharp discontinuity between areas in the somatosensory cortex that receive inputs from these digits (see [Figure 19-8](#)).

Neuronal Changes Associated With Learning Provide Insights Into Psychiatric Disorders

The demonstration that learning produces changes in the effectiveness of neural connections has revised our view of the relationship between social and biological processes in the shaping of behavior. Until recently the majority view in medicine and psychiatry was that biological and social determinants of behavior act on separate levels of the mind. For example, psychiatric illnesses were traditionally classified as either organic or functional. Organic mental illnesses included the dementias, such as Alzheimer disease, and the toxic psychoses, such as those that follow the chronic use of alcohol or cocaine. Functional mental illnesses included the various depressive syndromes, the schizophrenias, and the neuroses.

This distinction dates to the nineteenth century, when neuropathologists examined the brains of patients coming to autopsy and found gross and readily demonstrable distortions in the architecture of the brain in some psychiatric diseases but not in others. Diseases that produce anatomical evidence of brain lesions were called *organic*; those lacking these features were called *functional*.

The experiments reviewed in this chapter show that this distinction is no longer tenable. Everyday events—sensory stimulation, deprivation, and learning—can effectively weaken synaptic connections in some circumstances and strengthen them in others. We no longer think that only certain diseases (“organic diseases”) affect mentation through biological changes in the brain. The basis of contemporary neural science is that all mental processes are biological and therefore any alteration in those processes is necessarily organic.

In the attempt to understand the biological basis of a particular mental illness we must ask, to what degree is this biological process determined by genetic and developmental factors? To what degree is it determined by a toxic or infectious agent, or by a developmental abnormality? To what degree is it socially determined?

Even those mental disturbances that are considered most heavily determined by social factors must have a biological aspect, since it is the activity of the brain that is being modified. Insofar as social intervention works, whether through psychotherapy, counseling, or the support of family or friends, it must work by acting on the brain, quite likely on the strength of connections between nerve cells. Just because structural changes may not initially be detected following cognitive therapy does not rule out the possibility that important biological changes are nevertheless occurring. They may simply be below the level of detection with the limited techniques available to us.

Demonstrating the biological nature of mental functioning requires more sophisticated anatomical methodologies than the light-microscopic histology of nineteenth century pathologists. We must develop a neuropathology of mental illness based on functional as well as structural analysis. The new imaging techniques—positron emission tomography and functional magnetic resonance imaging, among others—have opened the door to the noninvasive exploration of the human brain on a cell-biological level, the level of resolution that is required to understand the physical mechanisms of mentation and therefore of mental disorders. This approach is now being pursued in the study of schizophrenia and depression

It is intriguing to think that insofar as psychotherapy is successful in changing behavior, it may do so by producing alterations in gene expression. If so, successful psychotherapeutic treatment of neurosis or character disorders should also produce structural changes in the nervous system. Thus, we face the attractive possibility that as brain imaging techniques improve, these techniques might ultimately be useful not only for diagnosing various neurotic illnesses but also for monitoring the progress of psychotherapy.

A Alteration in gene structure in inherited psychiatric disease: Schizophrenia

B Alteration in gene regulation in acquired psychiatric disease: Post-traumatic stress syndrome

Figure 63-20 Genetic and acquired illnesses both have a genetic component. Genetic illnesses result from the expression of altered genes or allelic variants, whereas acquired illnesses (*neuroses*) involve the modulation of gene expression by environmental stimuli as a result of learning, leading to the transcription of a previously inactive gene. The gene is illustrated as having two segments. A coding region is transcribed into a messenger RNA (mRNA) by an RNA polymerase. The mRNA in turn is translated into a specific protein. A regulatory segment consists of an enhancer region and a promoter region (see [Chapter 13](#), Box 13-1). In this example the RNA polymerase can transcribe the gene when the regulatory protein binds to the enhancer region. For the regulatory protein must first be phosphorylated before it can act on the enhancer. Only when it is phosphorylated can CREB bind the adapter protein, the *CREB binding protein* (CBP), which allows the phosphorylated form of CREB to interact with the transcriptional machinery.

A. Inherited disease such as schizophrenia. **1.** Under normal conditions the phosphorylated regulatory protein binds to the enhancer segment, thereby activating the transcription of the structural gene, leading to the production of the normal protein. **2.** A mutant form of the coding region of the structural gene, in which a thymidine (T) has been substituted for a cytosine (C), leads to transcription of an altered messenger RNA. This in turn produces an abnormal protein, giving rise to the disease state. This alteration in gene structure becomes established in the germ line, is heritable, and contributes to the disease.

B. Acquired disease such as post-traumatic stress syndrome. **1.** If the regulatory protein for a normal structural gene is not phosphorylated, it cannot bind to the promoter site and thus gene translation cannot be initiated. **2.** In this case a specific experience leads to the activation of serotonin (5-HT) and cAMP, which activate the cAMP-dependent protein kinase. The catalytic unit translocates to the nucleus and phosphorylates the regulatory protein CREB, which then can bind to the enhancer segment and thus initiate gene transcription. By this means an abnormal learning experience could lead to the expression of a protein that gives rise to symptoms of a neurotic disorder.

P.1276

P.1277

In studying the specific molecular changes that underlie memory storage, we should look for altered gene expression in abnormal as well as normal mental states. There is now substantial evidence that the susceptibility to major psychotic illnesses—schizophrenia and manic-depressive disorders—is heritable and is due to allelic variations. The cell-biological data on learning and long-term memory reviewed here suggest that neurotic illnesses, acquired by learning, also are likely to involve alterations of gene expression but alterations due to disordered regulation ([Figure 63-20](#)).

Development, hormones, stress, drug addiction, alcoholism, and learning are all factors that alter gene expression by modifying the binding of transcriptional regulatory proteins to each other and to the regulatory regions of genes. It is likely that at least some neurotic illnesses (or components of them), as well as various forms of drug addiction, result from reversible defects in gene regulation.

An Overall View

Studies on synaptic plasticity suggest there are two overlapping stages in the development and maintenance of synaptic strength. The first stage, the initial steps of synapse formation, occurs primarily early in development and is under the control of genetic and developmental processes. The second stage, the fine-tuning of developed synapses by experience, begins during late stages of development and continues to some degree throughout life. An attractive possibility is that the activity-dependent cellular mechanisms involved in the associative learning of the mature organism may be similar to the activity-dependent mechanisms at work during critical periods of development.

The ongoing modification of synapses throughout life means that all behavior of an individual is produced by genetic and developmental mechanisms acting on the brain—that everything the brain produces, from the most private thoughts to the most public acts, should be understood as a biological process. Environmental factors and learning bring out specific capabilities by altering either the effectiveness or the anatomical connections of existing pathways.

The synthesis of neurobiology, cognitive psychology, neurology, and psychiatry that we have emphasized throughout this book is filled with promise. Modern cognitive psychology has shown that the brain stores an internal representation of the world, while neurobiology has shown that this representation can be understood in terms

of individual nerve cells and their interconnections. This synthesis has given us a better perspective on perception, action, learning, and memory. It also provides us with a profound new biological insight into the nature of mental illnesses.

Although early behaviorist psychology led the way in exploring observable aspects of behavior, advances in modern cognitive psychology indicate that investigations that fail to consider brain mechanisms cannot adequately explain behavior. As recently as 10 years ago it would have been difficult to establish the existence of an internal representation directly, since internal mental processes were essentially inaccessible to experimental analysis. However, as we have seen throughout this book, cell biology, molecular biology, and brain imaging have now made biological experiments on elementary aspects of internal mental processes feasible.

Contrary to the expectations of some, biological analysis is unlikely to diminish our fascination with thinking or to make thinking trivial by reduction when we frame the issues in terms of molecular biology. Rather cell biology and molecular biology have expanded our vision, allowing us to perceive previously unanticipated interrelationships between biological and psychological phenomena.

The boundary between cognitive psychology and neural science is arbitrary and always changing. It has been imposed not by the natural contours of the disciplines, but by lack of knowledge. As our knowledge expands, the biological and behavioral disciplines will merge at certain points; it is at these points that our understanding of mentation will rest on more secure ground. As we have tried to illustrate in this book, the merger of biology and cognitive psychology is more than a sharing of methods and concepts. The joining of these two disciplines represents the emerging conviction that scientific descriptions of mentation at several different levels will all eventually contribute to a unified biological understanding of behavior.

Current Flow in Neurons

John Koester

THIS SECTION REVIEWS THE basic principles of electrical circuit theory. Familiarity with this material is important for understanding the equivalent circuit model of the neuron developed in [Chapters 5,6,7,8,9](#). The section is divided into three parts:

- The definition of basic electrical parameters.
- A set of rules for elementary circuit analysis.
- A description of current flow in circuits with capacitance.

Definition of Electrical Parameters

Potential Difference (V or E)

Electrical charges exert an electrostatic force on other charges: Like charges repel, opposite charges attract. As the distance between two charges increases, the force that is exerted decreases. Work is done when two charges that initially are separated are brought together:

Negative work is done if their polarities are opposite, and positive work if they are the same. The greater the values of the charges and the greater their initial separation, the greater the work that is done (work $\int f \cdot dr$, where f is electrostatic force and r is the initial distance between the two charges). Potential difference is a measure of this work. The potential difference between two points is the work that must be done to move a unit of positive charge (1 coulomb) from one point to the other, ie, it is the potential energy of the charge. One volt (V) is the energy required to move 1 coulomb a distance of 1 meter against a force of 1 newton.

Current (I)

A potential difference exists within a system whenever positive and negative charges are separated. Charge separation may be generated by a chemical reaction (as in a battery) or by diffusion between two electrolyte solutions with different ion concentrations across a permeability-selective barrier, such as a cell membrane. If a region of charge separation exists within a conducting medium, then charges move between the areas of potential difference: positive charges are attracted to the

P.1281

region with a more negative potential, and negative charges go to the regions of positive potential. The resulting movement of charges is current flow, which is defined as the net movement of positive charge per unit time. In metallic conductors current is carried by electrons, which move in the opposite direction of current flow. In nerve and muscle cells current is carried by positive and negative ions in solution. One ampere (A) of current represents the movement of 1 coulomb (of charge) per second.

Conductance (g)

Any object through which electrical charges can flow is called a conductor. The unit of electrical conductance is the siemen (S). According to Ohm's law, the current that flows through a conductor is directly proportional to the potential difference imposed across it.

$$I = V \times g$$

$$\text{Current (A)} = \text{Potential difference (V)} \times \text{Conductance (S)}$$

As charge carriers move through a conductor, some of their potential energy is lost; it is converted into thermal energy due to the frictional interactions of the charge carriers with the conducting medium.

Each type of material has an intrinsic property called conductivity (σ), which is determined by its molecular structure. Metallic conductors have very high conductivities; they conduct electricity extremely well. Aqueous solutions with high ionized salt concentrations have somewhat lower values of σ , and lipids have very low conductivities—they are poor conductors of electricity and are therefore good insulators. The conductance of an object is proportional to σ times its cross-sectional area, divided by its length:

$$g = (\sigma) \times \frac{\text{Area}}{\text{Length}}$$

The length dimension is defined as the direction along which one measures conductance.

For example, the conductance measured along the cytoplasmic core of an axon is reduced if its length is increased or its diameter decreased ([Figure A-1](#)).

Figure A-1 Geometric factors, together with intrinsic conductivity, determine the conductance of an object.

A. Conductance is inversely proportional to the length of a conductor.

B. Conductance is directly proportional to the cross-sectional area of a conductor.

Electrical resistance (R) is the reciprocal of conductance, and is a measure of the resistance provided by an object to current flow. Resistance is measured in ohms (Ω):

$$1 \text{ ohm} = (1 \text{ siemen})^{-1}.$$

Capacitance (C)

A capacitor consists of two conducting plates separated by an insulating layer. The fundamental property of a capacitor is its ability to store charges of opposite sign: positive charge on one plate, negative on the other.

A capacitor made up of two parallel plates with its two conducting surfaces separated by an insulator (an air gap) is shown in [Figure A-2A](#). There is a net excess of positive charges on plate x, and an equal number of excess negative charges on plate y, resulting in a potential difference between the two plates. One can measure this potential difference by determining how much work is required to move a positive test charge from the surface of y to that of x. Initially, when the test charge is at y, it is attracted by the negative charges on y, and repelled less strongly by the more distant positive charges on x. The result of these electrostatic interactions is a force f that opposes the movement of the test charge from y to x. As the test charge is moved to the left across the gap, the attraction by the negative charges on y diminishes, but the repulsion by the positive charges on x increases, with the result that the net electrostatic force exerted on the test charge is constant everywhere between x and y ([Figure A-2A](#)). Work (W) is force (f) times the distance (D) over which the force is exerted:

$$W = f \times D.$$

Therefore, it is simple to calculate the work done in moving the test charge from one side of the capacitor to the

P.1282

other. It is the shaded area under the curve in [Figure A-2A](#). This work is equal to the difference in electrical potential energy, or potential difference, between x and y.

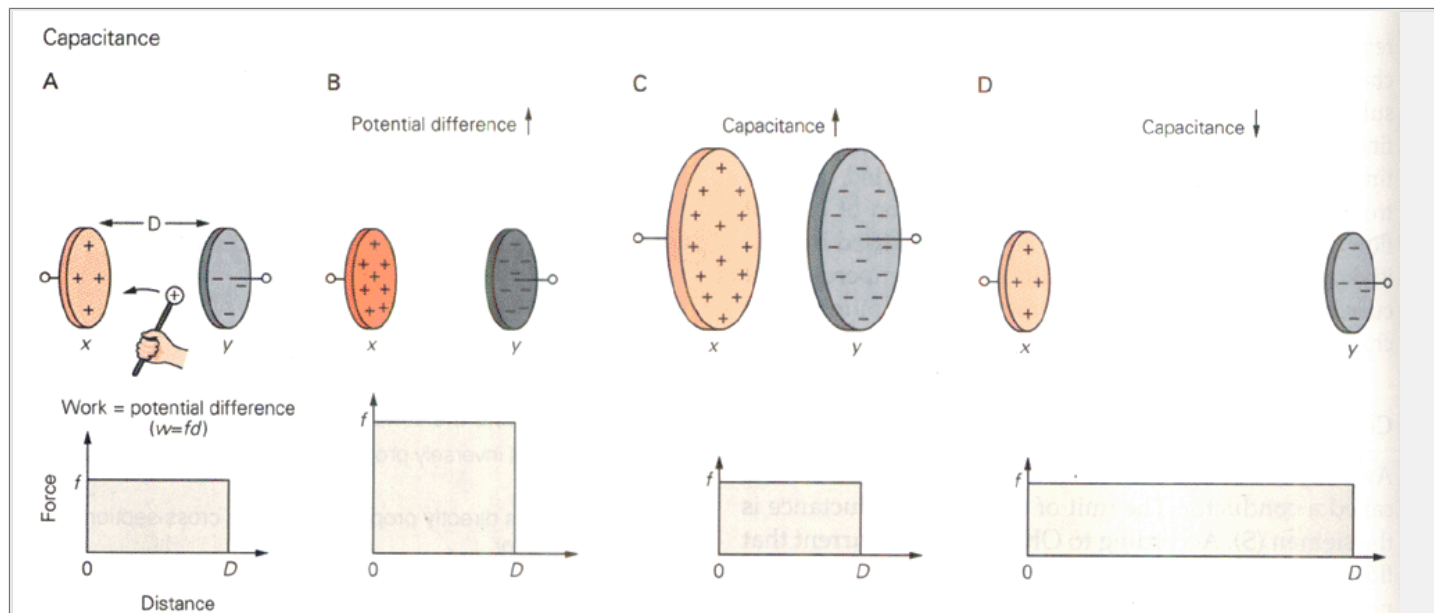

Figure A-2 The factors that affect the potential difference between two plates of a capacitor.

- A.** As a test charge is moved between two charged plates it must overcome a force. The work done against this force is the potential difference between the two plates.
- B.** Increasing the charge density increases the potential difference.
- C.** Increasing the area of the plates increases the number of charges required to produce a given potential difference.
- D.** Increasing the distance between the two plates increases the potential difference between them.

Capacitance is measured in farads (F). The greater the density of charges on the capacitor plates, the greater the force acting on the test charge, and the greater the resulting potential difference across the capacitor ([Figure A-2B](#)). Thus, for a given capacitor, there is a linear relationship between the amount of charge (Q) stored on its plates and the potential difference across it:

$$Q \text{ (coulombs)} = C \text{ (farads)} \times V \text{ (volts)} \quad (\text{A-1})$$

where the capacitance, C , is a constant.

The capacitance of a parallel-plate capacitor is determined by two features of its geometry: the area (A) of the two plates, and the distance (D) between them. Increasing the area of the plates increases capacitance, because a greater amount of charge must be deposited on each side to produce the same charge density, which is what determines the force f acting on the test charge ([Figure A-2A and C](#)). Increasing the distance D between the plates does not change the force acting on the test charge, but it does increase the work that must be done to move it from one side of the capacitor to the other ([Figure A-2A and D](#)). Therefore, for a given charge separation between the two plates, the potential difference between them is proportional to the distance. Put another way, the greater the distance the smaller the amount of charge that must be deposited on the plates to produce a given potential difference, and therefore the smaller the capacitance ([Equation A-1](#)). These geometrical determinants of capacitance can be summarized by the equation:

$$C \propto \frac{A}{D}$$

As shown in [Equation A-1](#), the separation of positive and negative charges on the two plates of a capacitor results in a potential difference between them. The converse of this statement is also true: The potential difference across a capacitor is determined by the excess of positive and negative charges on its plates. In order for the potential across a capacitor to change, the amount of electrical charges stored on the two conducting plates must change first.

Rules for Circuit Analysis

A few basic relationships that are used for circuit analysis are listed below. Familiarity with these rules will help in understanding the electric circuit examples that follow.

Conductance

The symbol for a conductor is:

Figure. No Caption Available.

P.1283

A variable conductor is represented this way:

Figure. No Caption Available.

A pathway with infinite conductance (zero resistance) is called a short circuit, and is represented by a line:

Figure. No Caption Available.

Conductances in parallel add:

Figure. No Caption Available.

Conductances in series add reciprocally:

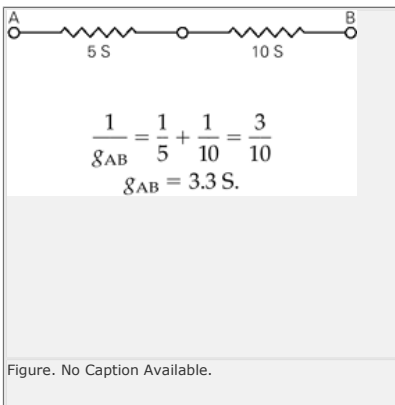

Figure. No Caption Available.

Resistances in series add, while resistances in parallel add reciprocally.

Current

An arrow denotes the direction of current flow (net movement of positive charge). Ohm's law is

$$I = V_g = \frac{V}{R}$$

When current flows through a conductor, the end that the current enters is positive with respect to the end that it leaves:

Figure. No Caption Available.

The algebraic sum of all currents entering or leaving a junction is zero (we arbitrarily define current approaching a junction as positive, and current leaving a junction as negative). In the following

Figure. No Caption Available.

the currents for junction x are:

$$\begin{aligned} I_A &= +5 \text{ A} \\ I_B &= -5 \text{ A} \\ I_A + I_B &= 0. \end{aligned}$$

In the following circuit

Figure. No Caption Available.

the currents for junction y are:

$$\begin{aligned} I_a &= +3 \text{ A} \\ I_b &= -2 \text{ A} \\ I_c &= -1 \text{ A} \\ I_a + I_b + I_c &= 0. \end{aligned}$$

P.1284

Current follows the path of greatest conductance (least resistance). For conductance pathways in parallel, the current through each path is proportional to its conductance value divided by the total conductance of the parallel combination:

Figure. No Caption Available.

$$I_T = 10 \text{ A}$$

$$g_a = 3 \text{ S}$$

$$g_b = 2 \text{ S}$$

$$g_c = 5 \text{ S}$$

$$I_a = I_T \frac{g_a}{g_a + g_b + g_c} = 3 \text{ A}$$

$$I_b = I_T \frac{g_b}{g_a + g_b + g_c} = 2 \text{ A}$$

$$I_c = I_T \frac{g_c}{g_a + g_b + g_c} = 5 \text{ A}.$$

Capacitance

The symbol for a capacitor is:

The potential difference across a capacitor is proportional to the charge stored on its plates:

$$V_C = \frac{Q}{C}.$$

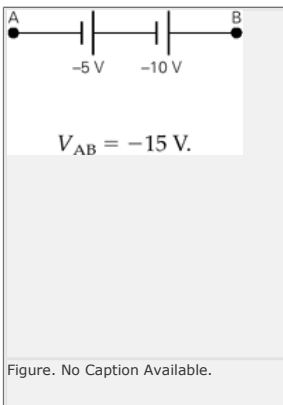

Potential Difference

The symbol for a battery, or electromotive force is:

It is often abbreviated by the symbol E. The positive pole is always represented by the longer bar.

Batteries in series add algebraically, but attention must be paid to their polarities. If their polarities are the same, their absolute values add:

If their polarities are opposite, they subtract:

Figure. No Caption Available.

The convention used here for potential difference is that $V_{AB} = (V_A - V_B)$.

A battery drives a current around the circuit from its positive to its negative terminal:

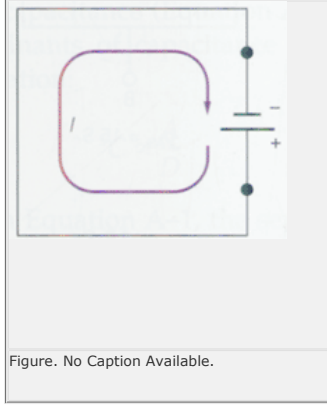

Figure. No Caption Available.

For purposes of calculating the total resistance of a circuit the internal resistance of a battery is set at zero.

The potential differences across parallel branches of a circuit are equal:

Figure. No Caption Available.

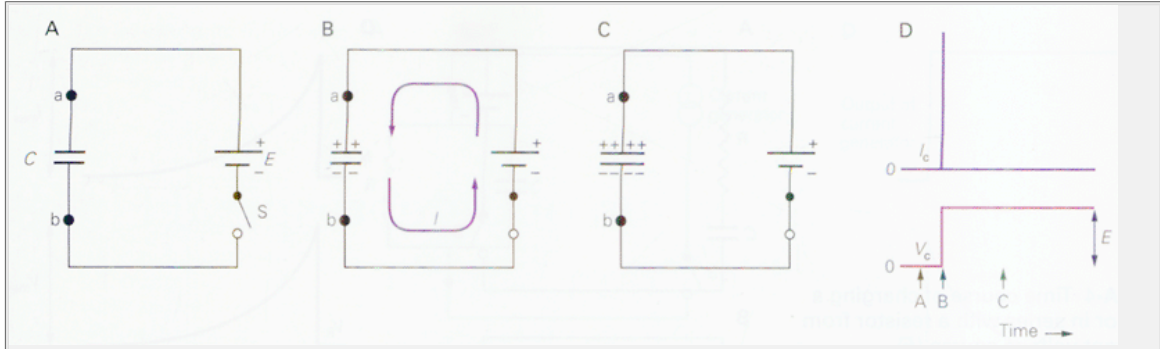

Figure A-3 Time course of charging a capacitor.

- A.** Circuit before the switch (S) is closed.
- B.** Immediately after the switch is closed.
- C.** After the capacitor has become fully charged.
- D.** Time course of changes in I_c and V_c in response to closing of the switch.

Figure. No Caption Available.

As one goes around a closed loop in a circuit, the algebraic sum of all the potential differences is zero:

$$2\text{ V} + 3\text{ V} + 5\text{ V} - 10\text{ V} = 0.$$

P.1285

Current Flow in Circuits With Capacitance

Circuits that have capacitive elements are much more complex than those that have only batteries and conductors. This complexity arises because current flow varies with time in capacitive circuits. The time dependence of the changes in current and voltage in capacitive circuits is illustrated qualitatively in the following three examples.

Circuit With Capacitor

Current does not actually flow across the insulating gap in a capacitor; rather it results in a build-up of positive and negative charges on the capacitor plates. However, we can measure a current flowing into and out of the terminal of a capacitor. Consider the circuit shown in [Figure A-3A](#). When switch S is closed ([Figure A-3B](#)), a net positive charge is moved by the battery E onto plate a, and an equal amount of net positive charge is withdrawn from plate b. The result is current flowing counterclockwise in the circuit. Since the charges that carry this current flow into or out of the terminals of a capacitor, building up an excess of plus and minus charges on its plates, it is called a capacitive current (I_c). Because there is no resistance in this circuit, the battery E can generate a very large amplitude of current, which will charge the capacitance to a value $Q = E \times C$ in an infinitesimally short period of time ([Figure A-3D](#)).

Circuit With Resistor and Capacitor in Series

Now consider what happens if a resistor is added in series with the capacitor in the circuit shown in [Figure A-4A](#). The maximum current that can be generated when switch S is closed ([Figure A-4B](#)) is now limited by Ohm's law ($I = V/R$). Therefore, the capacitor charges more slowly. When the potential across the capacitor has finally reached the value $V_c = Q/C = E$ ([Figure A-4C](#)), there is no longer a difference in potential around the loop, i.e., the battery voltage (E) is equal and opposite to the voltage across the capacitor, V_c . The two thus cancel out, and there is no source of potential difference left to drive a current around the loop. Immediately after the switch is closed the potential difference is greatest, so current flow is at a maximum. As the capacitor begins to charge, however, the net potential difference ($V_c = E$) available to drive a current becomes smaller, so that current flow is reduced. The result is that an exponential change in voltage and in current flow occurs across the resistor and the capacitor. Note that in this circuit resistive current must equal capacitive current at all times (see [Rules for Circuit Analysis](#), above).

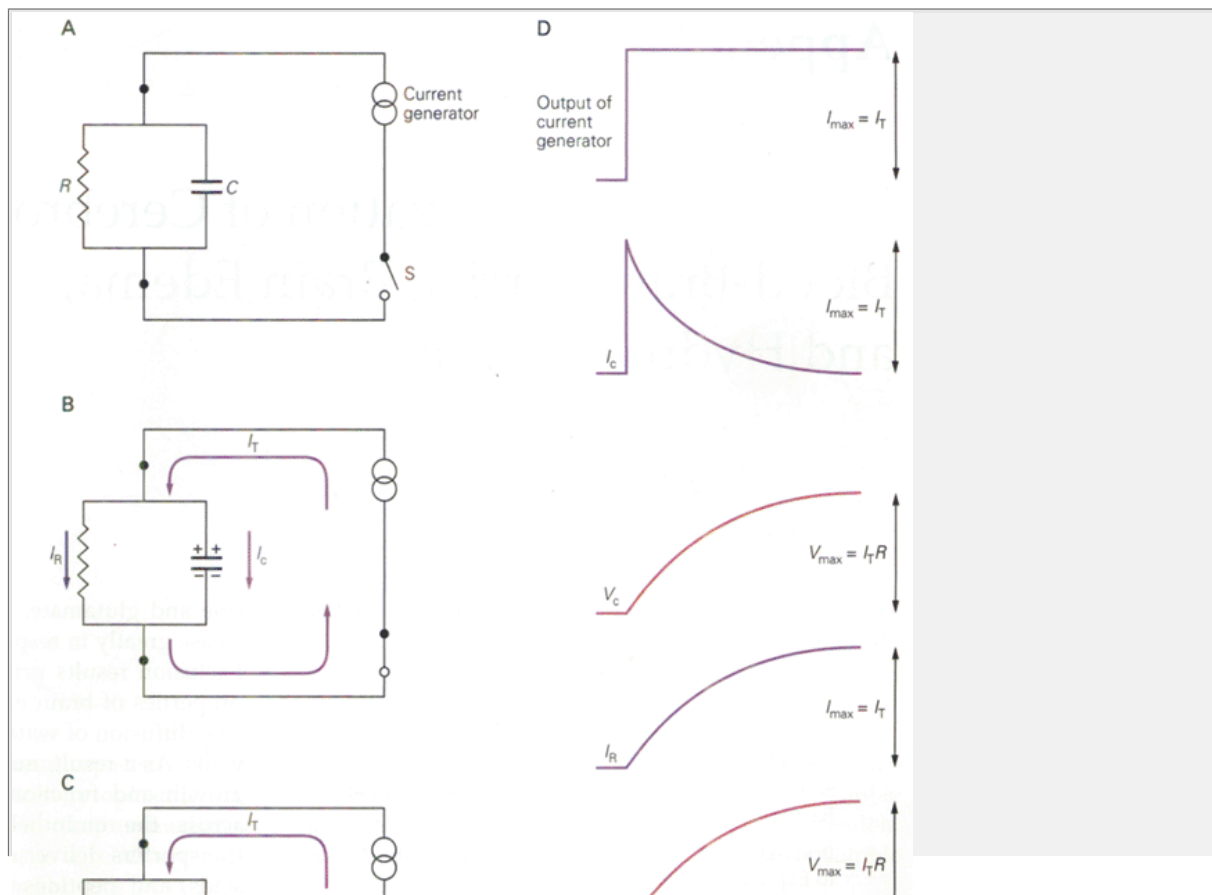

Circuit With Resistor and Capacitor in Parallel

Consider now what happens if we place a parallel resistor and capacitor combination in series with a constant

P.1286

P.1287

current generator that generates a current I_T ([Figure A-5A](#)). When switch S is closed current starts to flow around the loop. Initially, in the first instant of time after the current flow begins, all of the current flows into the capacitor, i.e., $I_T = I_c$. However, as charge builds up on the plates of the capacitor, a potential difference V_c is generated across it. Since the resistor and capacitor are in parallel, the potential across them must be equal; thus, part of the total current begins to flow through the resistors, such that $I_R R = V_c = V_c$ ([Figure A-5B](#)). As less and less current flows into the capacitor, its rate of charging will become slower; this accounts for the exponential shape of the curve of voltage versus time. Eventually, a plateau is reached at which the voltage no longer changes. When this occurs, all of the current flows through the resistor, and $V_c = V_R = I_T R$ ([Figure A-5C](#)).

Figure A-4 Time course of charging a capacitor in series with a resistor from a constant voltage source (E).

- B. Shortly after the switch is closed.
- C. After the charge deposited on the capacitor has reached its final value.
- D. Time course of changes in I_C , V_C , I_R , and V_R in response to closing of the switch.

Footnote

¹Note the analogy of this formula for current flow to the other formulas for describing flow; eg, bulk flow of a liquid due to a hydrostatic pressure; flow of a solute in response to a concentration gradient; flow of heat in response to a temperature gradient, etc. In each case flow is proportional to the product of a driving force times a conductance factor.

Appendix B

Ventricular Organization of Cerebrospinal Fluid: Blood-Brain Barrier, Brain Edema, and Hydrocephalus

John Laterra

Gary W. Goldstein

A BARRIER TO THE ENTRY of blood-borne substances to the brain has been recognized for at least a century. Evidence for the blood-brain barrier was first obtained in the nineteenth century, when it was observed that acidic vital dyes stain the brain if the dye is injected into the cerebrospinal fluid (CSF) but not if injected into the blood stream. This barrier maintains a stable environment for neurons to function effectively. It excludes many toxic substances and protects neurons from circulating neurotransmitters such as norepinephrine and glutamate, the blood levels of which can increase greatly in response to stress or even after a meal. Exclusion results primarily from specialized anatomic properties of brain endothelial cells that limit the passive diffusion of water-soluble substances across vessel walls. As a result, many metabolites required for brain growth and function must be transported selectively across the endothelial surface. Specific endothelial transporters deliver energy substrates, essential amino acids, and peptides from blood to brain and remove metabolites from the brain.

Differentiated Properties of Brain Capillary Endothelial Cells Account for the Blood-Brain Barrier

Anatomy of the Blood-Brain Barrier

Brain microvessels are composed of endothelial cells, pericytes with smooth muscle-like properties that reside adjacent to capillaries, and astroglial processes that ensheath more than 95% of the abluminal microvessel surface (Figure B-1). It was originally thought that the glial foot processes formed the blood-brain barrier, but electron-microscopic studies identified the endothelial cell as the principal anatomic site of the blood-brain barrier (Figure B-2).

The blood-brain barrier results from specialized properties of the endothelial cells, their intercellular junctions, and a relative lack of vesicular transport. In capillaries of peripheral organs and in the relatively few brain capillaries that do not form a barrier (eg, the circumventricular organs) blood-borne polar molecules

P.1289

diffuse passively across vessels through spaces between endothelial cells, through specialized cytoplasmic fenestrations, or by fluid-phase or receptor-mediated endocytosis. *Fluid-phase endocytosis* is a relatively nonspecific process by which endothelial cells (and most other cells) engulf and then internalize molecules encountered in the extracellular space by vesicular endocytosis. *Receptor-mediated endocytosis* is a specific process in which a ligand first binds to a membrane receptor on the external surface of the cell, is internalized by means of clathrin-coated vesicles, and is transported across the cell membrane. Once within the cell, the vesicle may fuse with an endosome and release its ligand.

Figure B-1 The ultrastructural features of the capillary endothelial cells of the brain differ from those of general (systemic) capillaries. The endothelial cells of barrier capillaries are relatively lacking in pinocytotic vesicles, contain an increased number of mitochondria believed to support energy-dependent transport properties, and are interconnected by very complex interendothelial tight junctions. These anatomic features in conjunction with specific transport systems (see Figure B-5) result in highly selective transport of water-soluble compounds across the barrier endothelium. Astrocyte foot processes almost completely surround the blood-brain barrier capillaries and are thereby believed to influence barrier-specific endothelial differentiation. In contrast, systemic capillaries have interendothelial clefts, fenestrae, and prominent pinocytotic vesicles. These features of systemic capillaries allow relatively nonselective diffusion across the capillary wall. (From Goldstein and Betz 1986.)

Endothelial cells of blood-brain barrier vessels are relatively deficient in vesicular transport. They also are not fenestrated. Instead they are interconnected by complex arrays of tight junctions (Figure B-2C). These junctions between the endothelial cells block diffusion across the vessel wall. All endothelial cells are interconnected by tight junctional complexes but normally have low resistance (5–10 ω/cm^2). In the vessels of the bloodbrain barrier, however, the resistance is very high (2000 ω/cm^2), and molecules as small as K^+ ions are excluded (Figure B-3).

Selectivity of the Blood-Brain Barrier

Normal development and brain function require a large number of compounds that must be able to cross brain microvessels. Entry into the CSF is achieved primarily in three ways: (1) by diffusion of lipid-soluble substances, (2) by facilitative and energy-dependent receptor-mediated transport of specific water-soluble substances, and (3) by ion channels.

Lipid-Soluble Substances

The brain is separated from blood only by a very large surface of endothelial cell membranes (approximately 180 cm^2/g in gray matter). This permits the efficient exchange of lipid-soluble gases such as O_2 and CO_2 , an exchange limited only by the surface area of the blood vessel and by cerebral blood flow. Barrier vessels are impermeable to poorly lipid-soluble molecules such as mannitol, as compared to very lipid-soluble compounds such as butanol. The permeability coefficient of the blood-brain barrier for many substances is directly proportional to the lipid solubility of the substance as measured by the oil-water partition coefficient (Figure B-4).

An example of this effect is in the correlation between the relative abuse potential of psychoactive drugs such as nicotine and heroin and the high oil-water partition coefficients of these drugs. Increasing the lipid solubility of pharmacologic agents within strict limits will enhance their delivery to the brain. Drugs with very high oil-water partition coefficients are poorly soluble in blood and bind to serum protein albumin, properties that reduce delivery to the brain. However, the permeability

P.1290

of some substances, such as glucose and vinca alkaloids, is not predicted accurately by the lipid solubility of the substance. This observation is explained by the presence of selective endothelial transport or enzyme systems that increase or inhibit substrate permeability.

Figure B-2 Interendothelial tight junctions are the basis of the anatomic blood-brain barrier.

- A.** When injected into arteries that supply the brain, the electron-dense tracer horseradish peroxidase is easily visualized within the brain vessel lumens (**dark staining**) at top but is excluded from entering the brain by interendothelial tight junctions (**TJ**). (From [Reese and Karnovsky 1967.](#))
- B.** When injected into the subarachnoid space, horseradish peroxidase readily diffuses between the perivascular astroglial foot processes and across the abluminal basement membrane (**BM**) but fails to penetrate interendothelial tight junctions (**TJ**). The luminal space appears at the top of the electron micrographs in both **A** and **B**. (From [Brightman and Reese 1969.](#))
- C.** Freeze-fracture photomicrograph of isolated brain microvessels, showing complex arrays of interendothelial tight junctions. (From [Shivers et al. 1984.](#))

Blood-Brain Barrier Transport Properties

Most substances that must cross the blood-brain barrier are not lipid soluble and therefore cross by specific carrier-mediated transport systems ([Figure B-5](#)). Because the brain uses glucose exclusively as its source of energy, the hexose transporter (glucose transporter isotype-1, Glut1) of the blood-brain barrier endothelial cells has been particularly well characterized.

Glut1 consists of 492 amino acids and has 12 putative transmembrane domains, similar to other transporters. It is a facilitative, saturable, and stereospecific transporter that functions at both the luminal and the abluminal endothelial cell membranes. Because it is not energy dependent, it cannot move glucose against a concentration gradient. The net flux of glucose is driven by the relatively higher concentration of glucose in plasma. Transport is half-saturated at glucose concentrations of 5 to 10 mM. More than 99% of the glucose molecules that enter blood-brain barrier endothelial cells are shuttled across for use by neurons and glia. The gene that codes for Glut1 resides on human chromosome 1. Whereas the complete absence of Glut1 is likely to be incompatible with life, deficient Glut1 expression

P.1291

is thought to be responsible for a rare clinical syndrome consisting of mental retardation, epilepsy, and persistent low CSF glucose concentration (ie, hypoglycorrhachia).

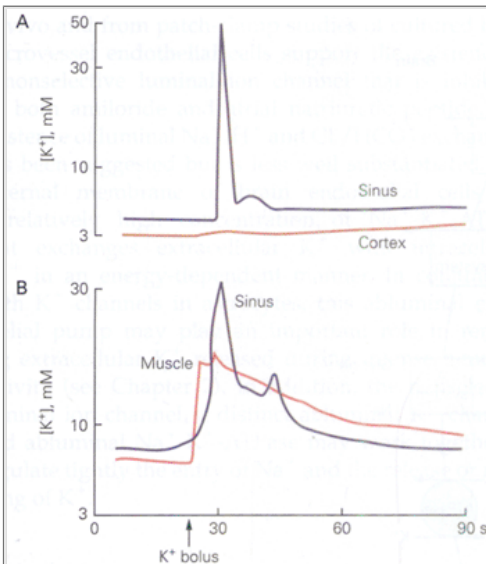

Figure B-3 Time course of K^+ concentration in the extracellular fluid of cerebral cortex (A), neck muscle (B), and sagittal sinus (A and B) following the bolus injection of KCl in the aortic arch. Note that the extracellular fluid K^+ concentration of cerebral cortex remains essentially unchanged because of the blood-brain barrier to ions. In contrast, K^+ diffuses rapidly across nonbarrier vessels into the extracellular space of muscle. (From [Hansen et al. 1977.](#))

Figure B-4 The oil-water partition coefficient indicates the relationship between lipid solubility and brain uptake of selected compounds. The distribution into olive oil relative to water for each test substance serves as a measure of its lipid solubility. The brain uptake is determined by comparing the extraction of each test substance relative to a highly permeable tracer during a single passage through the cerebral circulation. In general, compounds with higher oil-water partition coefficients show increased entry into brain. Uptake of the anticonvulsants phenobarbital and phenytoin is lower than predicted from their lipid solubility partly because of their binding to plasma proteins. This explains the slower onset of anticonvulsant activity of these agents compared to diazepam. Uptake of glucose and L-DOPA is greater than predicted by their lipid solubility because specific carriers facilitate their transport into the brain capillary. (From Goldstein and Betz 1986.)

Amino acids are transported across barrier endothelial cells primarily by three distinct carrier systems: the L system, the A system, and the ASC system. These carriers are characterized by their different patterns and mechanisms of transport, and by their preference for different amino acid analogs. Large neutral amino acids with branched or ringed side chains, such as leucine and valine, are transported primarily by the L system. The L system is a Na^+ -independent, facilitative transporter and is located at luminal and abluminal endothelial membranes. It can be inhibited experimentally by 2-aminobicycloheptane-2-carboxylic acid (BCH). Like glucose, large neutral amino acids are transported from blood down a concentration gradient. This carrier system transports systemically administered L-DOPA, the dopamine precursor that is the mainstay for treating Parkinson disease. Competitive inhibition of the transport of large neutral amino acids by elevated levels of phenylalanine may explain some of the neurotoxicity associated with untreated phenylketonuria, because phenylalanine is transported by the L system.

Glycine and neutral amino acids with short linear or polar side chains, such as alanine or serine, are preferentially transported by the A system. Unlike the L system, this carrier is energy dependent, Na^+ dependent, and experimentally inhibited by α -methylaminoisobutyric acid (MeAIB). The ASC system is also an energy-dependent and Na^+ -dependent transporter that preferentially recognizes alanine, serine, and cysteine. ASC-mediated transport is insensitive to both BCH and MeAIB. In contrast to the L carrier, the A and ASC transport systems are located exclusively at the abluminal endothelial cell surface. The physiological consequence of this localization is that the small neutral amino acids are transported primarily out of the brain up a concentration gradient through these carriers. The A system may limit the accumulation of the inhibitory neurotransmitter glycine within the spinal cord and the excitatory neurotransmitter glutamate within the brain. The energy and Na^+ exchange required for these systems is supplied by Na^+ -

P.1292

K^+ -ATPase, which also is localized to the abluminal endothelial membrane.

Figure B-5 A complex system of polarized transporter proteins and ionic channels determine the specific movement of water-soluble compounds and ions across barrier endothelial cells. Some transporters (eg, Glut1 and L system) facilitate the movement of substrates down concentration gradients, and others (eg, A system and Na^+ - K^+ -ATPase) actively transport substrates via energy-dependent mechanisms. Enzyme systems such as amino acid decarboxylase (AADC) and monoamine oxidase (MAO) function as a metabolic barrier by converting within the barrier endothelial cells substances such as L-DOPA to 3,4-dihydroxyphenylacetic acid.

Another transport system found to be most abundant in the blood-brain barrier microvessels belongs to a family of transmembranous proteins initially described for their ability to impart multiple drug resistance (MDR) to tumor cells. These transmembranous transporters remove a broad range of natural and synthetic hydrophobic toxins from cells that express the transporters. The MDR transporter (ie, p-glycoprotein) in the blood-brain barrier influences the delivery to the brain of many compounds used for cancer chemotherapy (eg, vinca alkaloids, actinomycin-D) and for other therapeutic purposes (eg, cyclosporin). Because p-glycoproteins pump certain steroid hormones, they may also have a physiological role. MDR transporters are expressed by blood-brain barrier microvessels but not by vessels of most other tissues. Mice genetically engineered to lack MDR1a gene expression no longer express blood-brain barrier p-glycoprotein and are much more sensitive than wild-type controls to centrally acting toxic compounds, indicating that MDR gene expression at the blood-brain barrier protects the brain from circulating neurotoxins.

Ion Channels and Exchangers

Specific ion channels and ion transporters mediate electrolyte movement across the blood-brain barrier. Evidence from transport studies across brain microvessels

P.1293

in vivo and from patch-clamp studies of cultured brain microvessel endothelial cells support the existence of a nonselective luminal ion channel that is inhibited by both amiloride and atrial natriuretic peptide. The existence of luminal Na^+/H^+ and $\text{Cl}^-/\text{HCO}_3^-$ exchangers has been suggested but is less well substantiated. The external membrane of brain endothelial cells has a relatively high

concentration of Na⁺-K⁺-ATPase that exchanges extracellular K⁺ with intracellular Na⁺ in an energy-dependent manner. In conjunction with K⁺ channels in astrocytes, this abluminal endothelial pump may play an important role in removing extracellular K⁺ released during intense neuronal activity (see [Chapter 2](#)). In addition, the nonselective luminal ion channel, a distinct abluminal K⁺ channel, and abluminal Na⁺-K⁺-ATPase may work together to regulate tightly the entry of Na⁺ and the release or recycling of K⁺.

The Metabolic Blood-Brain Barrier

Transport systems and carriers are not the only components that regulate the composition of the interstitial fluid. A similarly important role is also played by certain enzyme systems specific to the blood-brain barrier. The first recognized and still the best characterized example is the barrier to L-DOPA. Plasma L-DOPA enters brain endothelial cells by means of the L-system amino acid transporter. The relatively high amounts of DOPA decarboxylase and monoamine oxidase in endothelial cells of the barrier rapidly metabolize L-DOPA to 3,4-dihydroxyphenylacetic acid, thereby inhibiting the entry of L-DOPA to the brain ([Figure B-5](#)). This explains why effective Parkinson disease therapy requires that L-DOPA be given together with an inhibitor of DOPA decarboxylase. Other bloodborne amines, including catecholamines, are also inactivated by monoamine oxidases of the barrier endothelium. In addition to its proposed role in cystine transport, the abundant endothelial enzyme of the blood-brain barrier, γ -glutamyl transpeptidase, detoxifies glutathione-bound compounds and vasoactive leukotrienes.

Some Areas of the Brain Do Not Have a Blood-Brain Barrier

Not all cerebral blood vessels are entirely impermeable. Leaky areas include the posterior pituitary and circumventricular organs such as the area postrema, subfornical organ, the lamina terminalis, subcommissural organ, median eminence, and neurohypophysis. In the posterior pituitary most of the capillaries are fenestrated. Capillaries that are not fenestrated contain many cytoplasmic vesicles that are thought to transport substances across the endothelial cell. These structural features account for the enhanced transport across these cells.

The absence of a blood-brain barrier in these regions is consistent with their physiological functions. In the pituitary, neurosecretory products have to pass across endothelial cells into the circulation. The subfornical organ is a chemoreceptive area that monitors blood angiotensin II levels to regulate water balance and other homeostatic functions.

These leaky regions are isolated from the rest of the brain by specialized ependymal cells called *tanycytes* located along the ventricular surface close to the midline. The tanycytes are coupled by tight junctions and prevent free exchange between the circumventricular organs and the CSF.

Brain-Derived Signals Induce Endothelial Cells to Express Blood-Brain Barrier Properties

The cellular and molecular signals that induce endothelial expression of the blood-brain barrier phenotype have been elusive. The neural anlagen of the brain is vascularized very early in development through the invasion of proliferating vessels derived from an extraneural vascular plexus. These perineural vessels are composed of fenestrated endothelial cells that have no blood-brain barrier. Soon after penetrating neural tissue (within 2–4 days in the rat), fenestrations are lost. The subsequent expression of different blood-brain barrier properties on the endothelium occurs gradually, suggesting a maturational cascade.

The blood-brain barrier properties expressed by brain endothelial cells are believed to be induced by cells within the surrounding brain. Thus, barrier properties will develop in peripheral endothelial cells that invade brain tissue transplants but not in brain endothelial cells that invade peripheral tissue transplants. The cellular origin and biochemical nature of the brain parenchymal signals that induce endothelial barrier formation are not known but may originate from perivascular astroglia. Consistent with an important role for such parenchymal signals is the observation that brain endothelial cells rapidly lose their blood-brain barrier properties when isolated in culture and reexpress barrier properties when reimplanted in the central nervous system. Of the principal cell types that comprise the brain—neurons, oligodendroglia, and astroglia—astroglia are thought to be particularly important for

P.1294

this function because of their close association with the abluminal endothelial surface in mature brain. Astroglial cells, particularly in conjunction with cyclic adenosine monophosphate agonists, specifically increase the complexity of interendothelial tight junctions.

Figure B-6 Distribution of CSF. (Adapted from [Carpenter 1978](#) and [Fishman 1992](#).)

A. Sites of formation, circulation, and absorption of CSF. All spaces containing CSF communicate with each other. Choroidal and extrachoroidal sources of the fluid exist within the ventricular system. CSF circulates to the subarachnoid space and is absorbed into the venous system via the arachnoid villi. The presence of arachnoid villi adjacent to the spinal roots supplements the absorption into the intracranial venous sinuses. (Adapted from [Fishman 1992](#).)

B. The subarachnoid space is bounded externally by the arachnoid membrane and internally by the pia mater, which extends along blood vessels that penetrate the surface of the brain. (Adapted from [Carpenter 1978](#).)

Disorders of the Blood-Brain Barrier

A variety of pathological situations are associated with altered blood-brain barrier function. Many brain tumors contain vessels with a poorly developed blood-brain barrier. The least aggressive low-grade astrocytomas may contain vessels with close-to-normal barrier characteristics. In contrast, malignant primary tumors (ie, anaplastic astrocytoma, glioblastoma) and brain metastases of systemic cancers contain vessels that are excessively leaky and lack the differentiated transport properties of normal blood-brain barrier vessels. The abnormal vessel permeability accounts for the excessive accumulation of interstitial fluid (called *vasogenic edema*) commonly associated with brain tumors. The abnormal properties of tumor endothelial cells are presumably explained either by the absence of normal interactions between astrocytes and capillaries or by the secretion of factors by tumor cells. Vascular endothelial growth factor/vascular permeability factor is one such factor that may account for the excessive proliferation and permeability of the glioblastoma vessel.

Another condition in which the blood-brain barrier is altered is bacterial meningitis. The blood-brain barrier is normally impermeable to antibiotics such as penicillin. Bacterial meningitis, abscesses, and their associated inflammatory responses cause a partial breakdown of the barrier. This barrier response appears to be

P.1295

mediated in part by the accumulation of vasoactive eicosanoids and inflammatory cytokines such as tumor necrosis factor. Although this barrier dysfunction accounts for some of the adverse

neurological effects of these infections, it also results in an enhanced ability to deliver antibiotics to the site of infection within the brain.

Because the development and function of the normal brain is linked closely to specific anatomical, biochemical, and transport properties of the blood-brain barrier, specific defects in genes that code for barrier endothelial proteins might account for inherited brain disorders. The first developmental disorder of blood-brain barrier transport has been described. Patients with this syndrome are normal at birth but soon develop poorly controlled seizures, diminished brain growth, and mental retardation in association with a substantially diminished concentration of glucose in the CSF. Glucose enters the CSF through Glut1. This transporter is also found in red blood cells. In these patients red blood cell Glut1 is reduced by approximately 50%, suggesting that this syndrome is due to reduced Glut1 gene expression and a subsequent decrease in blood-to-brain glucose transport. The genetic basis for this disorder has yet to be fully defined.

Cerebrospinal Fluids Has Several Functions

CSF communicates with brain interstitial fluid and is therefore important in maintaining a constant external environment for neurons and glia. The primarily oneway flow of CSF from the ventricular system, around the spinal cord, into the subarachnoid space around the brain, and into the venous sinuses is a major route for removing potentially harmful brain metabolites. CSF also provides a mechanical cushion to protect the brain from impact with the bony calvarium when the head moves. By its buoyant action, CSF allows the brain to float, thereby reducing its effective weight in situ to less than 50 g. CSF may also serve as a lymphatic system for the brain and as a conduit for polypeptide hormones that are secreted by hypothalamic neurons and that act at remote sites in the brain. The pH of CSF affects both pulmonary ventilation and cerebral blood flow—another example of the homeostatic role of CSF.

Cerebrospinal Fluid Is Secreted by the Choroid Plexus

CSF is secreted in the lateral ventricles mainly by the choroid plexus (Figure B-6A), which consists of capillary networks surrounded by cuboidal or columnar epithelium. CSF flows from the lateral ventricles through the interventricular foramina of Monro into the third ventricle. From there it flows into the fourth ventricle through the cerebral aqueduct of Sylvius and then through the foramina of Magendie and Luschka into the subarachnoid space. The subarachnoid space lies between the arachnoid and the pia mater, which, together

P.1296

with the dura mater, form the three meningeal layers that cover the brain (Figure B-6B). Within the subarachnoid space, fluid flows down the spinal canal and also upward over the convexity of the brain (Figure B-6A).

CSF flowing over the brain extends into the sulci and the depths of the cerebral cortex in extensions of the subarachnoid space along blood vessels called *Virchow-Robin spaces*. Small solutes diffuse freely between the interstitial fluid and the CSF in these perivascular spaces and across the ependymal lining of the ventricular system, facilitating the movement of metabolites from deep within the hemispheres to cortical subarachnoid spaces and the ventricular system.

The total CSF volume has not been measured accurately but is estimated to be approximately 140 ml. The lateral and third ventricles contain approximately 12 ml, and the spinal subarachnoid space about 30 ml as measured by computerized tomography. The subarachnoid space and major cisterns (eg, cisterna magna and mesencephalic cistern) of the brain contain most of the CSF.

CSF is absorbed through the arachnoid granulations and villi. Arachnoid granulations consist of collections of villi. They are typically found in clusters that are visible herniations of the arachnoid membrane through the dura and into the lumen of the superior sagittal sinus and other venous structures (see Figure B-6A). The villi themselves are visible microscopically and separate CSF from venous blood. Cells of the villus membrane may actively form vacuoles that transport fluid from one side of the cell to the other (Figure B-7).

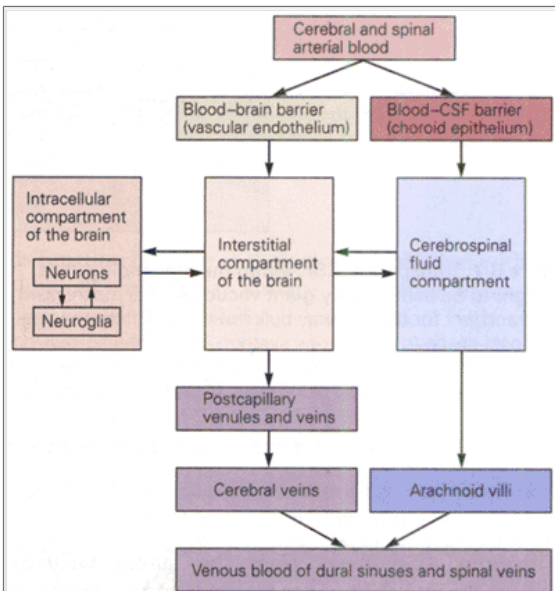

Figure B-8 Relationships between intracranial fluid compartments and the blood-brain and blood-CSF barriers. The tissue elements indicated in parentheses form the barriers. Arrows indicate the direction of fluid flow under normal conditions. (Adapted from Carpenter 1978.)

Table B-1 Comparison of Serum and Cerebrospinal Fluid

Component	CSF ¹	Serum ¹
Water content (%)	99	93
Protein (mg/dl)	35	7000
Glucose (mg/dl)	60	90
Osmolarity (mOsm/liter)	295	295
Na ⁺ (meq/liter)	138	138
K ⁺ (meq/liter)	2.8	4.5
Ca ²⁺ (meq/liter)	2.1	4.8
Mg ²⁺ (meq/liter)	0.3	1.7
Cl ⁻ (meq/liter)	119	102
pH	7.33	7.41

¹ Average or representative values. (From Fishman 1980.)

The granulations appear to function as valves that allow one-way flow of CSF from the subarachnoid spaces into venous blood. This one-way flow of CSF is sometimes called *bulk flow* because all constituents of CSF leave with the fluid, including small molecules, proteins, microorganisms, and red blood cells. The rate of formation of CSF in adults is 0.35 ml/minute or about 500 ml/day, so that the entire volume of CSF is turned over three to four times per day (Figure B-8).

The choroid plexus is structurally similar to the distal and collecting tubules of the kidney, using capillary filtration and epithelial secretory mechanisms to maintain the chemical stability of the CSF. The capillaries that traverse the choroid plexus are freely permeable to plasma solutes. A barrier exists, however, at the level of the epithelial cells that make up the choroid plexus. This barrier is responsible for carrier-mediated active transport (Figure B-9). The secretory capacities of the choroid plexus are bidirectional, accounting for both continuous production of CSF and active transport of metabolites out of the central nervous system into the blood.

CSF and extracellular fluids of the brain are in a steady state under normal physiological circumstances. The concentrations of K⁺, Ca²⁺, bicarbonate, and glucose in CSF are lower than in blood plasma, and CSF is

P.1297

also more acidic (Table B-1). These differences are due to regulation of the constituents of CSF by active transport. Under normal conditions, blood plasma and CSF are in osmotic equilibrium, because water follows the osmotic gradient created by active transport of solutes.

Figure B-9 Flow of molecules across the blood-CSF barrier is regulated by several mechanisms in choroid epithelial cells. Some micronutrients such as vitamin C are transported into epithelial cells by an energy-dependent active transporter located at the basolateral membrane and released into CSF at the apical surface by facilitated diffusion, which requires no energy. Essential ions are also exchanged between CSF and blood plasma. Transport of an ion in one direction is linked to the transport of a different ion in the opposite direction, as in the exchange of Na⁺ ions for K⁺ ions. (From [Spector and Johanson 1989](#).)

The Composition of Cerebrospinal Fluid May Be Altered in Disease

The gross appearance of the CSF has clinical significance. Normally it is clear and colorless. It may appear cloudy when it contains many leukocytes or has a high protein content. It may also appear grossly bloody or yellow (*xanthochromia*) when blood pigments are left behind after a hemorrhage or when its protein content is greater than 150 mg/dl, indicating that bilirubin (bound to albumin) has been brought from the plasma to the CSF.

Normal CSF does not contain red blood cells. White blood cell counts greater than 4/mm³ are pathological. In acute bacterial meningitis the count may be a thousandfold greater. Cells may be increased moderately in viral infections or in response to cerebral infarction, brain tumors, or other damage to cerebral tissue. Tumor cells in CSF can be collected and identified by their characteristic morphology and cell type-specific proteins.

Protein content may be increased by many pathological processes of the brain or spinal cord, because of changes in vascular permeability or changes in CSF dynamics due to altered function of choroid plexus or arachnoid granulations. In multiple sclerosis and a few other inflammatory diseases the γ -globulin content of CSF is disproportionately increased to more than 13% of total protein. When this increment in γ -globulin content of CSF is present without a corresponding increase in

P.1298

blood γ -globulin, it cannot be attributed to vascular leak and instead results from the production of immunoglobulins within the central nervous system. Similarly, detection by immunoelectrophoresis of two or more oligoclonal immunological species in CSF that are not present in serum indicates immune-mediated brain disease. Oligoclonal immunoglobulins are present in CSF in about 90% of patients with multiple sclerosis. Protein content greater than 500 mg/dl is usually a manifestation of a block in the spinal subarachnoid space by a solid tumor, meningeal cancer, or other compressing lesion.

The concentration of glucose in the CSF is decreased in acute bacterial infections but only rarely in viral infections. In chronic diseases a CSF glucose content less than 40 mg/dl is a symptom of a tumor in the meninges; of fungal, yeast, or tuberculosis infection; or of sarcoidosis. The basis for the reduced CSF glucose content is not yet understood. It may be due to impaired transport into CSF; excessive glycolysis by organisms, blood cells, tumor cells, or the brain itself; or combinations of these mechanisms.

Increased Intracranial Pressure May Harm the Brain

In considering the factors that regulate intracranial pressure, the cranium and spinal canal can be regarded as a closed system. According to the Monro-Kellie doctrine, an increase in the volume of any one of the contents of the calvarium—brain tissue, blood, CSF, or other brain fluids—will produce increased intracranial pressure because the bony calvarium rigidly fixes the total cranial volume. Mass lesions and their frequently associated interstitial edema commonly increase intracranial pressure. Changes in arterial and intracranial venous pressures may also influence intracranial pressure by their actions on intracranial blood volume and CSF dynamics. Acute changes in arterial or venous pressures can change intracranial pressure dramatically. Chronic changes may be compensated for by several mechanisms, including venous collateralization and increased absorption or decreased formation of CSF.

CSF pressure is ordinarily measured by *lumbar puncture*, a procedure in which a needle is inserted through the skin, between the fourth and fifth lumbar vertebrae, and into the lumbar subarachnoid space, with the patient lying sideways (lateral decubitus position). Because the spinal cord extends only to the first lumbar vertebra, there is no risk of injuring the cord. When the CSF flows freely through the needle, the hub of the needle is attached to a manometer and the fluid is allowed to rise. The normal pressure is 65–195 mm CSF (or water) or 5–15 mm Hg.

In measuring the lumbar CSF pressure as a guide to intracranial pressure, it is assumed that pressures are equal throughout the neuraxis. Normally this is a reasonable assumption; however, in many disease states (eg, brain tumor or obstruction of CSF pathways) this may not be true. For this reason, and also because the lumbar needle cannot be left in place for prolonged periods, catheters are sometimes inserted into the lateral ventricles to measure the pressure there ([Figure B-10](#)).

P.1299

Equally effective are pressure-sensitive transducers that can be inserted under the skull in the epidural or subarachnoid space for continuous monitoring of intracranial pressure. Continuous monitoring has the advantage of identifying transient elevations in intracranial pressure that can occur in certain disorders such as normal pressure hydrocephalus.

Brain Edema Is A State Of Increased Brain Volume Due To Increased Water Content

Brain edema may be local (eg, from a surrounding contusion, infarct, or tumor) or generalized. The brain is divided into distinct compartments by relatively noncompliant membranes. Local brain edema may cause herniation of brain tissue across these membranes from one compartment into another. Specific examples include herniation of cingulate gyrus across the falx cerebri, temporal lobe uncus across the cerebellar tentorium, or the cerebral cortex through calvarial defects after surgery.

Vasogenic edema is the most common form of brain edema. It is attributed to increased permeability of brain capillary endothelial cells, which increases the volume of the extracellular fluid. White matter is generally affected more than gray because of the tendency of edema fluid to accumulate along tracts of white matter. Vasogenic edema is most easily visualized using T2-weighted magnetic resonance imaging. Pathological increases in blood-brain barrier permeability also can be visualized by computerized tomography and magnetic resonance imaging after intravenous administration of contrast agents that selectively enter the brain through the affected vessels. Pathologically increased blood brain barrier permeability, particularly that associated with brain tumors, can be corrected by systemically administered glucocorticoids. The mechanism by which glucocorticoids enhance blood-brain barrier function is poorly understood.

Cytotoxic edema refers to the intracellular swelling of injured neurons, glia, and endothelial cells. It occurs in hypoxia from asphyxia or global cerebral ischemia after cardiac arrest because failure of the ATP-dependent Na⁺-K⁺ pump allows Na⁺, and therefore water, to accumulate within cells. Another cause of cytotoxic edema is water intoxication, a consequence of the acute systemic hyposmolality caused by excessive ingestion of water or administration of hypotonic intravenous fluids. Acute hyponatremia, induced for example by inappropriate secretion of antidiuretic hormone or renal saltwasting from secretion of atrial natriuretic hormone, can cause cellular swelling and brain edema. Under these circumstances water moves from extracellular to intracellular sites. Cytotoxic edema may also accompany vasogenic edema in encephalitis, trauma, and stroke.

Hydrocephalus Is An Increase In The Volume Of The Cerebral Ventricles

Hydrocephalus has three possible causes: oversecretion of CSF, impaired absorption of CSF, or obstruction of CSF pathways.

Oversecretion of CSF is rare but is thought to occur in some functioning tumors of the choroid plexus (*papillomas*) because removal of the tumor may relieve the hydrocephalus. These tumors are associated with subarachnoid hemorrhage and high CSF protein content, which could also impair the absorption of CSF.

Impaired absorption of CSF may result from any condition that raises intracranial pressure, such as thrombosis of cerebral veins or sinuses. Impaired CSF absorption at the arachnoid villi is a common cause of *communicating hydrocephalus* (enlargement of the entire ventricular system without obstruction of CSF flow) following subarachnoid hemorrhage, trauma, or bacterial meningitis.

Impaired CSF absorption is also believed to be the cause of **normal-pressure hydrocephalus**, which is characterized by dementia, urinary incontinence, and a disorder of gait called *apraxia*. Brain imaging reveals communicating hydrocephalus, and routine lumbar puncture typically shows normal intracranial pressure. Continuous intracranial pressure monitoring reveals episodic elevations in intracranial pressure, however, suggesting that intermittent intracranial hypertension causes the condition.

Cisternography reveals alterations in the flow of CSF in these patients. In normal patients technetiumlabeled albumin injected into the lumbar subarachnoid space can be traced by a gamma camera up to the cortical convexities where the arachnoid granulations are located; however, the label does not enter the ventricles. In patients with normal-pressure hydrocephalus the isotopic label reaches the cortical convexities after a prolonged delay and may reflux into the ventricles. If identified early, normal-pressure hydrocephalus can be treated surgically by shunting CSF using a ventriculoperitoneal catheter.

Obstruction of CSF pathways may result from tumors, congenital malformations, or scarring. A particularly vulnerable site for all three mechanisms is the narrow aqueduct of Sylvius. Aqueductal stenosis may result from congenital malformations or gliosis due to

P.1300

intrauterine infection or hemorrhage. Later in life the aqueduct may be occluded by tumor. The outlets of the fourth ventricle may be obstructed by congenital atresia of the foramina of Luschka and Magendie, which may lead to enlargement of all four ventricles (Dandy-Walker syndrome). In early life the cranial vault enlarges with the ventricles; after the sutures fuse, cranial volume is fixed and hydrocephalus develops at the expense of brain volume.

Appendix C

Circulation of the Brain

John C.M. Brust

THE BRAIN IS HIGHLY vulnerable to disturbance of its blood supply. Anoxia and ischemia lasting only seconds cause neurological symptoms and when they last minutes they can cause irreversible neuronal damage.

Blood flow to the central nervous system must efficiently deliver oxygen, glucose, and other nutrients and remove carbon dioxide, lactic acid, and other metabolic products. The cerebral vasculature has unique anatomical and physiological features that protect the brain from circulatory compromise. When these protective mechanisms fail, the result is a stroke. Broadly defined, the term *stroke*, or *cerebrovascular accident*, refers to the neurological symptoms or signs, usually focal and acute, that result from diseases involving blood vessels.

The Blood Supply Of The Brain Can Be Divided Into Arterial Territories

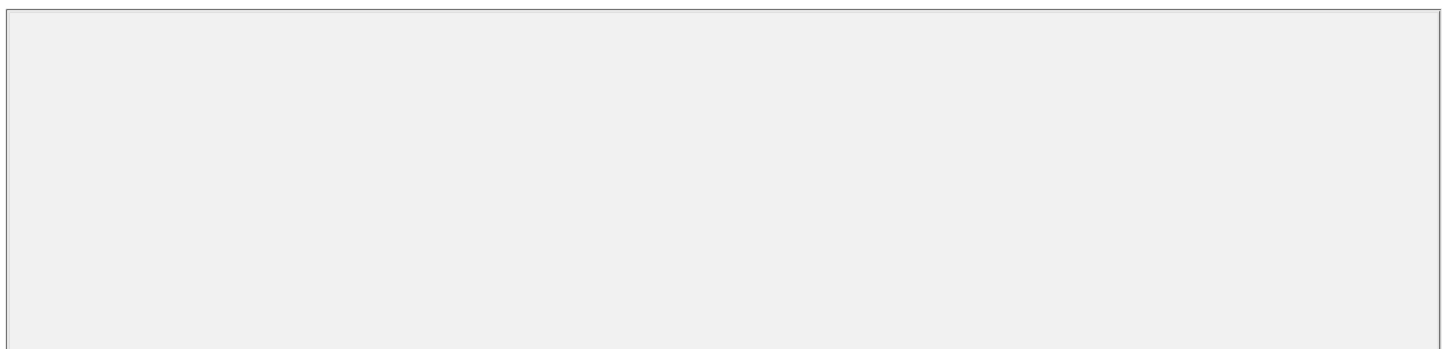

Each cerebral hemisphere is supplied by an *internal carotid artery*, which arises from a common carotid artery beneath the angle of the jaw, enters the cranium through the carotid foramen, traverses the cavernous sinus (giving off the *ophthalmic artery*), penetrates the dura, and divides into the anterior and middle cerebral arteries ([Figure C-1](#)).

The large surface branches of the *anterior cerebral artery* supply the cortex and white matter of the inferior frontal lobe, the medial surface of the frontal and parietal lobes, and the anterior corpus callosum. Smaller penetrating branches—including the so-called *recurrent artery of Heubner*—supply the deeper cerebrum and diencephalon, including limbic structures,

P.1303

P.1304

the head of the caudate, and the anterior limb of the internal capsule.

Figure C-1 The blood vessels of the brain. The circle of Willis is made up of the proximal posterior cerebral arteries, the posterior communicating arteries, the internal carotid arteries just before their bifurcations, the proximal anterior cerebral arteries, and the anterior communicating artery. *Dark areas* show common sites of atherosclerosis and occlusion.

Figure C-2 Cerebral arterial areas.

The large surface branches of the *middle cerebral artery* supply most of the cortex and white matter of the hemisphere's convexity, including the frontal, parietal, temporal, and occipital lobes, and the insula. Smaller penetrating branches (the *lenticulostriate arteries*) supply the deep white matter and diencephalic structures, such as the posterior limb of the internal capsule, the putamen, the outer globus pallidus, and the body of the caudate. After the internal carotid emerges from the cavernous sinus, it also gives off the *anterior choroidal artery*, which supplies the anterior hippocampus and, at a caudal level, the posterior limb of the internal capsule.

Left and right vertebral arteries arise from the subclavian arteries and enter the cranium through the foramen magnum. Each gives off an *anterior spinal artery* and a *posterior inferior cerebellar artery*. The vertebral arteries join at the junction of the pons and the medulla to form the *basilar artery*, which at the level of the pons gives off the *anterior inferior cerebellar artery* and the *internal auditory artery* and at the midbrain the *superior cerebellar artery*. The basilar artery then divides into the two *posterior cerebral arteries*, which supply the inferior temporal and medial occipital lobes and the posterior corpus callosum. The smaller penetrating branches of these vessels (the *thalamoperforate* and *thalamogeniculate arteries*) supply diencephalic structures, including the thalamus and the subthalamic nuclei, as well as parts of the midbrain.

These arterial territories are shown schematically in [Figure C-2](#). Infarctions in the territories of the anterior, middle, and posterior cerebral arteries are shown in [Figures C-3](#), [C-4](#), and [C-5](#).

Interconnections between blood vessels (*anastomoses*) protect the brain when part of its vascular supply is blocked ([Figure C-6](#)). At the *circle of Willis* the two anterior cerebral arteries are connected by the anterior communicating artery, and the posterior cerebral arteries are connected to the internal carotid arteries by the posterior communicating arteries. The circle of Willis provides an overlapping blood supply. A congenitally incomplete circle, which is common in the general population, is much more frequent among patients who have had strokes. Other important anastomoses include connections between the ophthalmic artery and branches of the external carotid artery through the orbit, and connections at the brain surface between branches of the middle, anterior, and posterior cerebral arteries (*sharing border zones* or *watersheds*). The small penetrating vessels arising from the circle of Willis and proximal major arteries tend to lack anastomoses. The deep brain regions they supply are therefore referred to as *end zones*.

P.1305

The Cerebral Vessels Have Unique Physiological Responses

Although the human brain constitutes only 2% of total body weight, it receives about 15% of the cardiac output and consumes approximately 20% of the oxygen used by the entire body. These values reflect the high metabolic rate and oxygen requirements of the brain. The total blood flow to the brain is about 750–1000 ml/min; about 350 ml of this amount flows through each carotid artery and about 100–200 ml flows through the vertebrasilar system. Flow per unit mass of gray matter is approximately four times that of white matter.

Cerebral vessels are capable of altering their own diameter and can respond in a unique fashion to altered physiological conditions. Two main types of autoregulation exist. Brain arterioles constrict when the systemic blood pressure is raised and dilate when it is lowered. These adjustments help to maintain optimal cerebral blood flow. The result is that normal individuals have a constant cerebral blood flow between mean arterial pressures of approximately 60–150 mm Hg. Above or below these pressures cerebral blood flow rises or falls linearly.

The second type of autoregulation involves blood or tissue gases and pH. When arterial CO₂ is raised, brain arterioles dilate and cerebral blood flow increases; with hypocarbia, vasoconstriction results and cerebral blood flow decreases. The response is very sensitive: inhalation of 5% CO₂ increases cerebral blood flow by 50%; 7% CO₂ doubles it. Changing arterial O₂ causes an opposite and less pronounced response: Breathing 100% O₂ lowers cerebral blood flow by about 13%; 10% O₂ raises it by 35%. The mechanism of these responses is uncertain. The vasodilatory action of arterial CO₂ is probably mediated by alterations in extracellular pH. Local concentrations of K⁺ and adenosine, both of which cause vasodilation in animals, may play a role.

Whatever the mechanism, these responses protect the brain by increasing the delivery of oxygen and the removal of acid metabolites in the presence of hypoxia, ischemia, or tissue damage. They also allow nearly instantaneous adjustments of regional cerebral blood flow to meet the demands of rapidly changing oxygen and glucose metabolism that accompany normal brain activities. For example, viewing a complex scene will increase oxygen and glucose consumption in the visual

P.1306

cortex of the occipital lobes. The resulting increased CO₂ concentration and lowered pH in the area cause an immediate local increase in blood flow.

A Stroke Is the Result of Diseases Involving Blood Vessels

Diseases of the blood vessels are among the most frequent serious neurological disorders, ranking third as a cause of death in the adult population in the United States and probably first as a cause of chronic functional incapacity. Approximately two million people in the United States today are impaired by the neurological consequences of cerebrovascular disease. Many of them are between 25 and 64 years of age.

Strokes are either *occlusive* (due to closure of a blood vessel) or *hemorrhagic* (due to bleeding from a vessel). Insufficiency of blood supply is termed *ischemia*; if it is temporary, symptoms and signs may clear with little or no pathological evidence of tissue damage. Ischemia is not synonymous with *anoxia*, for a reduced blood supply deprives tissue not only of oxygen but also of glucose. In addition, it prevents the removal of potentially toxic metabolites such as lactic acid. When ischemia is sufficiently severe and prolonged, neurons and other cellular elements die; this condition is called

infarction.

Hemorrhage may occur at the brain surface (*extraparenchymal*), for example, from rupture of congenital aneurysms at the circle of Willis, causing subarachnoid hemorrhage. Alternatively, hemorrhage may be *intraparenchymal*—for example, from rupture of vessels damaged by long-standing hypertension—and may cause a blood clot or *hematoma* within the cerebral hemispheres, in the brain stem, or in the cerebellum. Hemorrhage may result in ischemia or infarction. The mass effect of an intracerebral hematoma may limit the blood supply of adjacent brain tissue. By mechanisms that are not understood, subarachnoid hemorrhage may cause reactive vasospasm of cerebral surface vessels, leading to further ischemic brain damage.

Although most occlusive strokes are due to atherosclerosis and thrombosis and most hemorrhagic strokes are associated with hypertension or aneurysms, strokes of either type may occur at any age from many causes, including cardiac disease, trauma, infection, neoplasm, blood dyscrasia, vascular malformation, immunological disorder, and exogenous toxins. Diagnostic strategies and treatment should vary accordingly; however, in this appendix we examine the anatomical and physiological principles relevant to any occlusive or hemorrhagic stroke.

Clinical Vascular Syndromes May Follow Vessel Occlusion, Hypoperfusion, Or Hemorrhage

Infarction Can Occur in the Middle Cerebral Artery Territory

Infarction in the territory of the middle cerebral artery (cortex and white matter) causes the most frequently encountered stroke syndrome, with contralateral weakness, sensory loss, and visual field impairment (*homonymous hemianopsia*), and, depending on the hemisphere involved, either language disturbance or impaired spatial perception. Weakness and sensory loss affect the face and arm more than the leg because of the somatotopy of the motor and sensory cortex (pre- and postcentral gyri). The face- and arm-control areas are on the convexity, whereas the leg-control area is on the medial surface of the hemisphere. Motor and sensory loss are greatest in the hand, for the more proximal limbs and the trunk tend to have greater representation in both hemispheres. Paraspinous muscles, for example, are

P.1307

rarely weak in unilateral cerebral lesions. Similarly, the facial muscles of the forehead and the muscles of the pharynx and jaw are represented in both hemispheres and therefore are usually spared. Tongue weakness is variable. If weakness is severe (*plegia*), muscle tone is usually decreased at first but gradually increases over days or weeks to spasticity with hyperactive tendon reflexes. A Babinski sign, reflecting upper motor neuron disturbance (see [Chapters 33](#) and [38](#)), is usually present from the outset. When weakness is mild, or during recovery, there may be clumsiness or slowness of movement out of proportion to loss of strength; such motor disability may resemble parkinsonian bradykinesia or even cerebellar ataxia.

Figure C-6 Angiograms demonstrating the importance of anastomoses in that they allow retrograde filling after occlusion of the middle cerebral artery.

- A.** Occlusion of the middle cerebral artery results in no filling in the middle cerebral distribution.
- B.** Retrograde filling of the middle cerebral artery has begun via distal anastomotic branches of the anterior cerebral artery.
- C.** Retrograde filling of the middle cerebral artery continues at a time when little contrast material is seen in the anterior cerebral artery. (Courtesy of Dr. Margaret Whelan and Dr. Sadek K. Hilal.)

Acutely, paresis of contralateral conjugate gaze often occurs as a result of damage to the convexity of the cortex anterior to the motor cortex (the frontal eye field). The reason this gaze palsy persists for only 1 or 2 days, even when other signs remain severe, is not clear.

Sensory loss tends to involve discriminative and proprioceptive modalities more than affective modalities. Pain and temperature sensation may be impaired or altered but are usually not lost. Joint position sense, however, may be severely disturbed, causing limb ataxia, and there may be loss of two-point discrimination, *astereognosis* (inability to recognize a held object by tactile sensation), or *extinction* (failure to appreciate a touch stimulus if a comparable stimulus is delivered simultaneously to the unaffected side of the body).

Homonymous hemianopsia is the result of damage to the optic radiations, the deep fiber tracts connecting the thalamic lateral geniculate body to the visual (*calcarine*) cortex. If the parietal radiation is

primarily affected, the visual field loss may be an inferior quadrantanopia, whereas in temporal lobe lesions quadrantanopia may be superior.

In more than 95% of right-handed persons and in the majority of those who are left handed, the left hemisphere is dominant for language. Destruction of left opercular (*perisylvian*) cortex in left-dominant individuals causes aphasia, which may take several forms de-

P.1308

pending on the degree and distribution of the damage. Frontal opercular lesions tend to produce particular difficulty with speech output and writing with relative preservation of language comprehension (*Broca aphasia*), whereas infarction of the posterior superior temporal gyrus tends to cause severe difficulty in speech comprehension and reading (*Wernicke aphasia*). When opercular damage is widespread, there is severe disturbance of mixed type (*global aphasia*).

Left-hemisphere convexity damage, especially parietal, may also cause motor apraxia, a disturbance of learned motor acts not explained by weakness or incoordination, with the ability to perform the act when the setting is altered (see [Chapters 19](#) and [59](#)). For example, a patient unable to imitate lighting a match might be able to perform the act normally if given a match to light.

Right-hemisphere convexity infarction, especially parietal, tends to cause disturbances of spatial perception. Patients may have difficulty in copying simple pictures or diagrams (*constructional apraxia*), in interpreting maps or finding their way about (*topographagnosia*), or in putting on their clothing properly (*dressing apraxia*). Awareness of space and the patient's own body contralateral to the lesion may be particularly affected (*hemi-inattention* or *hemineglect*). Patients may fail to recognize their hemiplegia (*anosognosia*), left arm (*asomatognosia*), or any external object to the left of their own midline. Such phenomena may occur independently of visual field defects and in patients otherwise mentally intact (see [Chapter 20](#)).

Particular types of language or spatial dysfunction tend to follow occlusion not of the proximal stem of the middle cerebral artery but of one of its several main pial branches. In such circumstances other signs (eg, weakness or visual field defect) may not be present. Similarly, occlusion of the rolandic branch of the middle cerebral artery may cause motor and sensory loss affecting the face and arm without disturbance of vision, language, or spatial perception.

Infarction Can Occur in the Anterior Cerebral Artery Territory

Infarction in the territory of the anterior cerebral artery causes weakness and sensory loss qualitatively similar to that of convexity lesions, but infarction in this territory affects mainly the distal contralateral leg. Urinary incontinence may be present, but it is uncertain whether this is because of a lesion of the paracentral lobule (medial hemispheric motor and sensory cortices) or of a more anterior region necessary for the inhibition of bladder emptying. Damage to the supplementary motor cortex may cause speech disturbance, considered aphasia by some and a type of motor inertia by others. Involvement of the anterior corpus callosum may cause apraxia of the left arm (*sympathetic apraxia*), which is attributed to disconnection of the left (language-dominant) hemisphere from the right motor cortex.

Bilateral anterior cerebral artery territory infarction (occurring, for example, when both arteries arise anomalously from a single trunk) may cause a severe behavioral disturbance, known as *abulia*, consisting of profound apathy, motor inertia, and muteness, and attributable to destruction, in variable combinations, of the inferior frontal lobes (orbitofrontal cortex), deeper limbic structures, supplementary motor cortices, and cingulate gyri.

Infarction Can Occur in the Posterior Cerebral Artery Territory

Infarction in the territory of the posterior cerebral artery causes contralateral homonymous hemianopsia by destroying the calcarine cortex. Macular (central) vision tends to be spared because the occipital pole, where macular vision is represented, receives blood supply from the middle cerebral artery. If the lesion is on the left and the posterior corpus callosum is affected, *alexia*—inability to read—may be present without aphasia or agraphia. A possible explanation for the alexia is the disconnection of the seeing right occipital cortex from the language-dominant left hemisphere. If infarction is bilateral (eg, following thrombosis at the point where both posterior cerebral arteries arise from the basilar artery), there may be cortical blindness with failure of the patient to recognize that he cannot see (*Anton syndrome*), or memory disturbance may occur as a result of bilateral damage to the inferomedial temporal lobes.

If posterior cerebral artery occlusion is proximal, the lesion may include, or especially affect, the following structures: the thalamus, causing contralateral hemisensory loss and sometimes spontaneous pain and dysesthesia (*thalamic pain syndrome*); the subthalamic nucleus, causing contralateral severe proximal chorea (*hemiballism*); or even the midbrain, with ipsilateral oculomotor palsy and contralateral hemiparesis or ataxia from involvement of the corticospinal tract or the crossed superior cerebellar peduncle (dentatothalamic tract).

The Anterior Choroidal and Penetrating Arteries Can Become Occluded

Anterior choroidal artery occlusion can cause contralateral hemiplegia and sensory loss from involvement of

P.1309

the posterior limb of the internal capsule and homonymous hemianopsia from involvement of the thalamic lateral geniculate nucleus.

As mentioned earlier in this chapter, the deeper cerebral white matter and diencephalon are supplied by small penetrating arteries, variously called the *lenticulostriates*, the *thalamogeniculates*, or the *thalamoperforates*, which arise from the circle of Willis or the proximal portions of the middle, anterior, and posterior cerebral arteries. These end-arteries lack anastomotic interconnections, and occlusion of individual vessels, usually in association with hypertensive damage to the vessel wall, causes small (less than 1.5 cm in diameter) infarcts (*lacunes*), which, if critically located, are followed by characteristic syndromes. For example, lacunes in the pyramidal tract area of the internal capsule cause *pure hemiparesis*, with arm and leg weakness of equal severity and with little or no sensory loss, visual field disturbance, aphasia, or spatial disruption. Lacunes in the ventral posterior nucleus of the thalamus produce pure hemisensory loss, with involvement of pain, temperature, proprioceptive, and discriminative modalities and with little motor, visual, language, or spatial disturbance. Most lacunes occur in redundant areas (eg, nonpyramidal corona radiata) and so are asymptomatic. If bilateral and numerous, however, they may cause a characteristic syndrome (*état lacunaire*) of progressive dementia, shuffling gait, and pseudobulbar palsy (spastic dysarthria and dysphagia, with lingual and pharyngeal paralysis and hyperactive palate and gag reflexes, plus lability of emotional response, with abrupt crying or laughing out of proportion to mood).

Infarction restricted to structures supplied by the recurrent artery of Heubner or other deep penetrating branches of the anterior cerebral artery (the anterior caudate nucleus and less predictably the anterior putamen and anterior limb of the internal capsule) results in varying combinations of psychomotor slowing, dysarthria, agitation, contralateral neglect, and, when left hemispheric, language disturbance.

The Carotid Artery Can Become Occluded

Atherothrombotic vessel occlusion often occurs in the internal carotid artery rather than the intracranial vessels. Particularly in a patient with an incomplete circle of Willis, infarction may include the territories of both the middle and anterior cerebral arteries, with arm and leg weakness and sensory loss equally severe. Alternatively, infarction may be limited to the distal shared territory (border zones of these vessels), producing, by destruction of the motor cortex at the upper cerebral convexity, weakness limited to the arm or the leg. Another cause of leg weakness and sensory loss in association with a convexity syndrome is occlusion of the middle cerebral artery at its proximal stem; the internal capsule and other diencephalic structures supplied by the middle cerebral artery's lenticulostriate branches are then affected in addition to the cortex of the cerebral convexity.

The Brain Stem and Cerebellum Are Supplied by Branches of the Vertebral and Basilar Arteries

Branches of the vertebral and basilar arteries consist of three sets: (1) Paramedian branches, including the anterior spinal artery, supply midline structures; (2) short circumferential branches supply more lateral structures, including the inferior, middle, and superior cerebral peduncles; and (3) long circumferential arteries—the posterior inferior, anterior inferior, and superior cerebellar arteries—also supply lateral brain stem structures and the cerebellar peduncles, as well as the cerebellum itself. Most of the midbrain is supplied by branches of the posterior cerebral artery. The interpeduncular branches, the most medial branches located between the basilar artery bifurcation and the posterior communicating arteries, supply paramedian midbrain structures. Lateral to this group are the thalamoperforate branches, which supply the inferior, medial, and anterior thalamus and the subthalamic nucleus. Further laterally are the thalamogeniculate branches, which supply lateral and dorsal structures in the midbrain and thalamus. In some people the midbrain also receives blood from the superior cerebellar, posterior communicating, and anterior choroidal arteries. After the posterior cerebral artery passes around the midbrain, it enters the middle fossa to supply the occipital and inferior temporal lobes. It does not supply the cerebellum.

Various syndromes resulting from damage to specific brain stem structures have been defined ([Figure C-7](#)). With the exception of the lateral medullary syndrome of Wallenberg, however, most of the original descriptions were based on patients with neoplasms. Brain stem infarction more often follows occlusion of the vertebral or basilar arteries themselves than of their medial or lateral branches; resulting syndromes and signs tend to be less stereotyped than classical descriptions imply.

Generally speaking, a lesion of the posterior fossa is suggested by (1) bilateral long tract (motor or sensory) signs, (2) crossed (eg, left face and right limb) motor or sensory signs, (3) cerebellar signs, (4) stupor or coma (from involvement of the ascending reticular activating system), (5) disconjugate eye movements or nystagmus, and (6) involvement of cranial nerves not usually affected by unilateral hemispheric infarcts (eg, unilateral

P.1310

deafness or pharyngeal weakness). Sometimes a lesion involving only a single tiny structure can be localized accurately by symptomatology. For example, internuclear ophthalmoplegia implicates a lesion of the median longitudinal fasciculus. Other lesions produce more ambiguous symptoms. For example, infarction limited to the upper pontine corticospinal tract can produce contralateral face, arm, and leg weakness indistinguishable from that caused by a small infarct in the internal capsule.

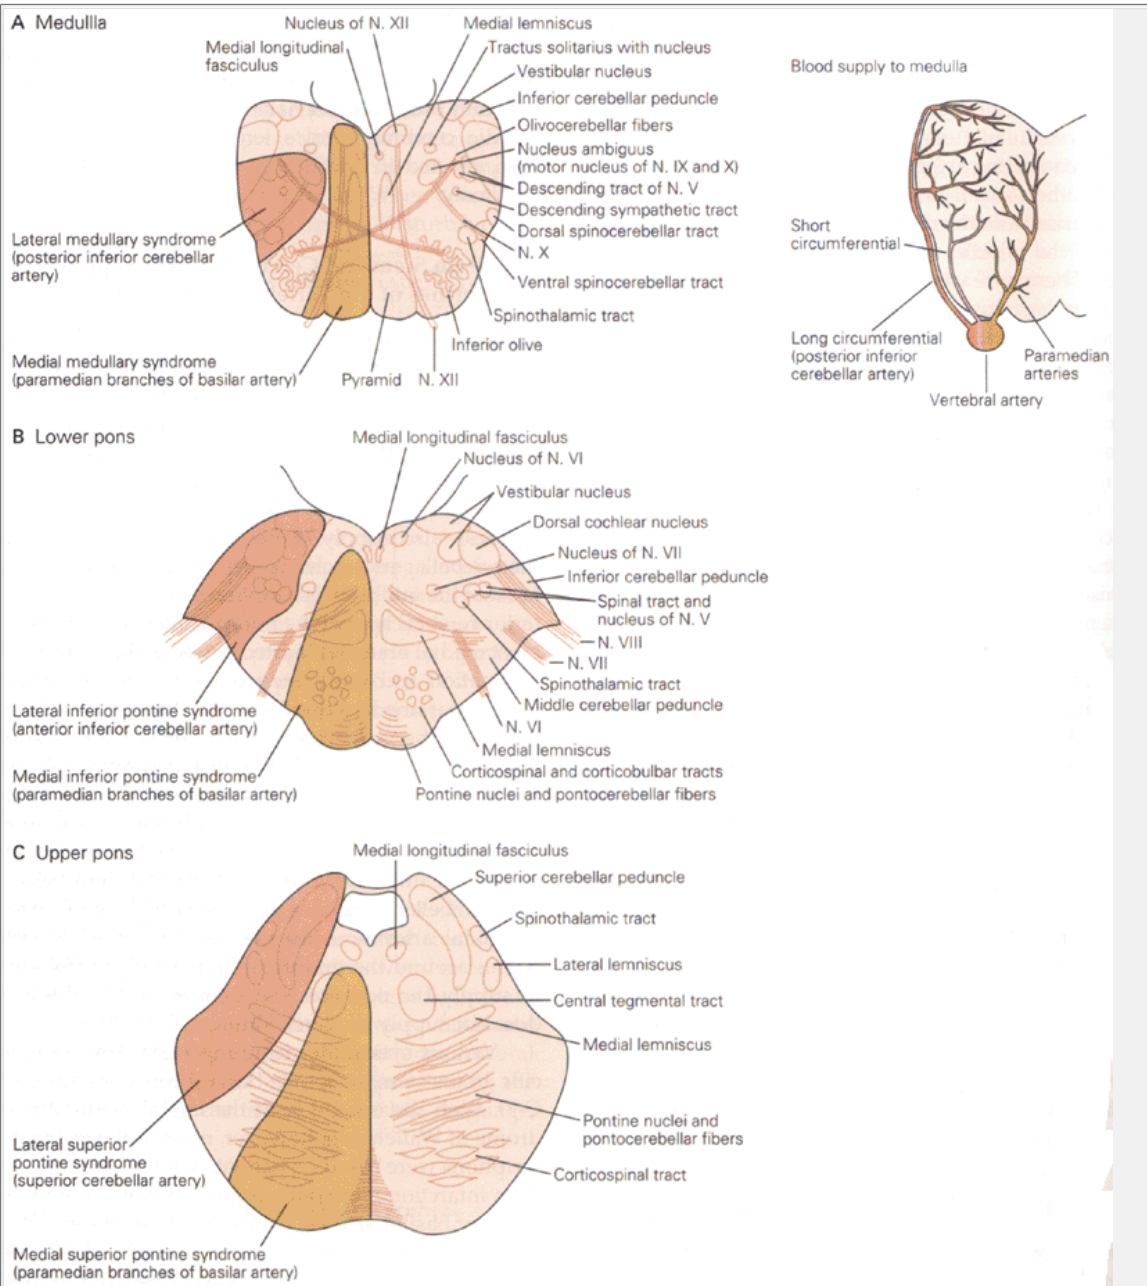

Figure C-7 Syndromes of brain stem vascular lesions (indicated on the left in each figure).

Figure C-8 Magnetic resonance imaging shows a white highlight in the ventral portion of one half of the pons. The lesion stops abruptly at the midline, suggesting unilateral occlusion of one or more paramedian vessels.

Infarcts Affecting Predominantly Medial or Lateral Brain Stem Structures Produce Characteristic Syndromes

Infarction of the lateral medulla follows occlusion of the vertebral artery or less often the posterior inferior cerebellar artery. Symptoms and signs include (1) vertigo, nausea, vomiting, and nystagmus (from involvement of the vestibular nuclei); (2) ataxia of gait and ipsilateral limbs (inferior cerebellar peduncle or the cerebellum itself); (3) decreased pain and temperature (but not touch) sensation on the ipsilateral face (descending tract and nucleus of the trigeminal nerve) the contralateral body (spinothalamic tract); (4) dysphagia, hoarseness, ipsilateral weakness of the palate and vocal cords, and ipsilaterally decreased gag reflex (nucleus ambiguus, or glossopharyngeal and vagus outflow tracts); and (5) ipsilateral Horner syndrome (descending sympathetic fibers). Involvement of the nucleus solitarius can cause ipsilateral loss of taste, and hiccups are often present (Table C-1).

Infarction of the medial medulla causes contralateral hemiparesis (from involvement of the corticospinal tract), ipsilateral tongue weakness with dysarthria and deviation toward the paretic side (hypoglossal nucleus or outflow tract), and contralateral impaired proprioception and discriminative sensation with preserved pain and temperature sensation (medial lemniscus).

Infarction of the lateral pons affects caudal structures when the anterior inferior cerebellar artery is occluded and rostral structures when the superior cerebellar artery is occluded (Figure C-8). Symptoms of caudal damage resemble those of lateral medullary infarction, with vertigo, nystagmus, gait and ipsilateral limb ataxia, crossed face-and-body pain and temperature loss, Horner syndrome, and ipsilateral loss of taste. There is also unilateral tinnitus and deafness (from involvement of the cochlear nuclei). Involvement of more medial structures can cause ipsilateral gaze paresis or facial weakness. Symptoms of rostral damage include gait and ipsilateral limb ataxia, Horner syndrome, and crossed sensory loss, which at this level includes touch, pain, and temperature sensation on the ipsilateral face (from involvement of the primary sensory nucleus or entering sensory fibers of the trigeminal nerve). There may also be ipsilateral jaw weakness with deviation to the paretic side (trigeminal motor nucleus and outflow tract). Vertigo, deafness, and face weakness are not present.

Infarction of the medial pons, whether caudal or rostral, causes contralateral hemiparesis (from involvement of the corticospinal tract). Caudal lesions affecting the facial nucleus or outflow tract cause ipsilateral facial weakness. Rostral lesions result in contralateral facial weakness. There may also be ipsilateral gaze paresis (paramedian pontine reticular formation or abducens nucleus, together comprising the *pontine gaze center*) or abducens paresis (sixth nerve outflow tract); internuclear ophthalmoplegia and limb and gait ataxia are often present. Contralateral impairment of proprioception and discriminative touch is most prominent with caudal lesions. Rapid involuntary movements of the palate—so-called *palatal myoclonus*—has been attributed to involvement of the central tegmental tract; their involuntary movements may spread to include the pharynx, larynx, face, eyes, or respiratory muscles.

Table C-1 Signs That Indicate the Level of Brain Stem Vascular Syndromes			
Syndrome	Artery affected	Structure involved	Manifestations
Medial syndromes			
Medulla	Paramedian branches	Emerging fibers of twelfth nerve	Ipsilateral hemiparalysis of tongue
Inferior pons	Paramedian branches	Pontine gaze center Emerging fibers of sixth nerve	Paralysis of gaze to side of lesion Ipsilateral abduction paralysis
Superior pons	Paramedian branches	Medial longitudinal fasciculus	Internuclear ophthalmoplegia
Lateral syndromes			
Medulla	Posterior inferior cerebellar	Emerging fibers of ninth or tenth nerves Vestibular nuclei Descending tract and nucleus of fifth nerve Solitary nucleus and tract	Dysphagia; hoarseness; ipsi-lateral paralysis of vocal cord; ipsilateral loss of pharyngeal reflex Vertigo; nystagmus Ipsilateral facial analgesia Taste loss on ipsilateral half of tongue posteriorly
Inferior pons	Anterior inferior cerebellar	Emerging fibers of seventh nerve Solitary nucleus and tract Cochlear nuclei	Ipsilateral facial paralysis Taste loss on ipsilateral half of tongue anteriorly Deafness; tinnitus
Mid pons		Motor nucleus of fifth nerve Emerging sensory fibers of fifth nerve	Ipsilateral jaw weakness Ipsilateral facial numbness

P.1312

Syndromes of midbrain infarction are more conveniently characterized as peduncular (ventral), tegmental, or pretectal/tectal (dorsal) (Figure C-9). Unilateral peduncular lesions cause *Weber syndrome*, characterized by ipsilateral paresis of adduction and vertical gaze and pupillary dilation (involvement of oculomotor nerve outflow tract) and contralateral face, arm, and leg paresis (corticospinal and corticobulbar tracts). Unilateral tegmental lesions cause *Claude syndrome*, characterized by oculomotor paresis (oculomotor nucleus) and contralateral ataxia and tremor (often referred to as *rubral tremor* but probably the result of damage to the brachium conjunctivum). Lesions affecting both the peduncle and tegmentum produce combinations of oculomotor paresis, ataxia, and weakness (*Benedikt syndrome*). Dorsal midbrain lesions, which are infrequently vascular and rarely unilateral, cause *Parinaud syndrome*, characterized by impaired vertical gaze—especially upward (posterior commissure and the rostral interstitial nucleus of the median longitudinal fasciculus)—and loss of the pupillary light reflex (pretectal structures).

Bilateral Brain Stem Lesions Can Have Devastating Consequences

Bilateral paramedian infarction of the upper brain stem can involve the reticular activating system and cause obtundation or coma. Bilateral damage of the proximal posterior cerebral artery produces altered consciousness and various combinations of mesencephalic, diencephalic, and cortical signs (*top of the basilar artery syndrome*), affecting eye movements, pupils, vision

P.1313

(including, even without visual loss, vivid formed hallucinations), sensation, coordination, memory, and behavior (including agitated delirium).

Bilateral corticospinal tract infarction causes quadriplegia or quadriparesis; additional cranial weakness depends on how rostral or caudal the lesion is. Bilateral infarction of the rostral basis pontis (with sparing of the tegmentum) produces paralysis of all muscles except eye movements, the so-called *locked-in state*. Such a patient may appear comatose yet is awake and able to communicate through eye movements. Less severe damage to the corticospinal tracts in the rostral brain stem can cause pseudobulbar palsy, with spastic quadriparesis, dysarthria, dysphagia, a hyperactive gag reflex, and for reasons unclear, labile emotional responses with explosive crying or laughing.

Infarction Can Be Restricted to the Cerebellum

Infarcts of the inferior cerebellum, which has extensive vestibular connections, can cause vertigo, nausea, and nystagmus without other symptoms, suggesting disease of the inner ear or vestibular nerve. (Similar symptoms, with or without tinnitus or deafness, can occur following occlusions of the internal auditory artery, arising from the basilar artery and supplying the peripheral labyrinth.) More superior cerebellar infarcts produce gait and ipsilateral limb ataxia.

Infarction Can Affect the Spinal Cord

The ventral spinal cord is supplied by a single anterior spinal artery; the dorsal spinal cord is supplied by two or more posterior spinal arteries (Figure C-10). Except most rostrally, where the anterior spinal artery arises from the joining of two vertebral artery branches, the anterior and posterior spinal arteries are fed along their course by several radicular arteries, which arise from segmental branches of the aorta and iliac arteries. Moreover, whereas the posterior spinal arteries are longitudinally continuous and anastomotic, the anterior spinal artery's continuity is tenuous, making the anterior spinal cord more dependent on its segmental supply. The upper thoracic spinal cord is especially vulnerable in this regard.

Vascular anatomy explains the characteristic pattern of spinal cord infarction. Vessel occlusion is usually in a proximal segmental artery; because of the anastomotic continuity of the posterior spinal arteries, infarction tends to be limited to the anterior spinal artery territory. There is paraparesis or quadriparesis (corticospinal tracts), loss of bladder and bowel control, and loss of pain and temperature sensation below the lesion (spinothalamic tracts), but proprioception and discriminative touch (dorsal columns) are spared. If the cervical or lumbar spinal cord is involved, atrophic weakness of upper or lower extremity muscles (anterior horns) can occur. Because the anterior spinal artery gives off sulcal arteries that alternately enter the left and right halves of the spinal cord, infarction can sometimes produce a *Brown-Séquard syndrome*, with ipsilateral weakness and contralateral loss of pain and temperature sensation.

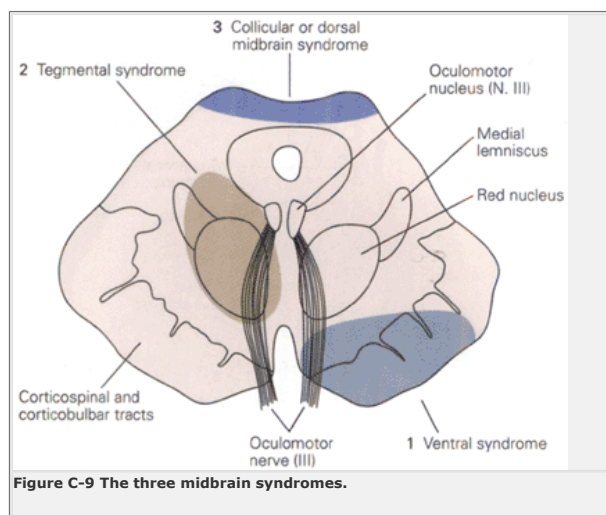

Figure C-9 The three midbrain syndromes.

Diffuse Hypoperfusion Can Cause Ischemia or Infarction

Brain ischemia or infarction may accompany diffuse hypoperfusion (shock). In such circumstances the most vulnerable regions are often the border zones between large arterial territories and the end

zones of deep penetrating vessels. Whatever the cause of reduced cerebral perfusion, signs tend to be bilateral. Paralysis and sensory loss may be present in both arms (from bilateral infarction of the cortex at the junction of the middle and anterior arterial supply, affecting the arm-control area of the motor and sensory cortex).

Disturbed vision or memory may result (from infarction of the occipital or temporal lobes at the junction of the middle and posterior cerebral arterial supply). There may also be ataxia (from cerebellar border-zone infarction) or abnormal movements such as chorea or myoclonus (presumably from involvement of the basal ganglia). Such signs may exist alone or in combination and may be accompanied by a variety of aphasic or other cognitive disturbances.

P.1314

Hypotension can also cause spinal cord infarction, most often upper thoracic, affecting either the territory of the anterior spinal artery or the border zone between the anterior and posterior spinal arteries.

Figure C-10 Diagram of the major sources of blood supply to the spinal cord. Anterior spinal rami are not shown

Cerebrovascular Disease Can Cause Dementia

Cerebral infarction causes dementia by a number of mechanisms, including:

- Infarcts may be critically located. For example, thalamic or inferomedial temporal damage (posterior cerebral artery, usually bilateral) can cause amnesia; hemispheric convexity damage (middle cerebral artery) can cause cognitive or behavioral impairment not explained by disruption of language or spatial discrimination; and bilateral inferomedial frontal lobe damage (anterior cerebral artery) can cause abulia and impaired memory.
- Multiple scattered infarcts, none sufficient to cause significant cognitive loss, can produce additive effects culminating in dementia. In such patients at least 100 cc of brain volume has usually been destroyed.
- Small vessel disease, affecting especially the deep cerebral white matter, can cause either scattered lacunes or more diffuse ischemic lesions. When such lesions are severe enough to cause dementia—so-called *Binswanger disease*—altered behavior, pseudobulbar palsy, pyramidal signs, disturbed gait, and urinary incontinence usually occur.

P.1315

The Rupture of Microaneurysms Causes Intraparenchymal Stroke

The two most common causes of hemorrhagic stroke, hypertensive intra-axial hemorrhage and rupture of a saccular aneurysm, tend to occur at particular sites and to cause recognizable syndromes. Hypertensive intracerebral hemorrhage is the result of damage to the same small penetrating vessels that, when occluded, cause lacunes; in the case of hemorrhage, however, the damaged vessels develop weakened walls (*Charcot-Bouchard microaneurysms*) that eventually rupture. The most common sites are the putamen, thalamus, pons, internal capsule and corona radiata, and cerebellum. Large diencephalic hemorrhages tend to cause stupor and hemiplegia and have a high mortality rate.

With lesions of the putamen the eyes are usually deviated ipsilaterally (because of disruption of capsular pathways descending from the frontal eye field), whereas with thalamic hemorrhage the eyes tend to be deviated downward and the pupils may not react to light (because of involvement of midbrain pretectal structures essential for upward gaze and pupillary light reactivity). Small hemorrhages may not impair alertness, and, with small thalamic hemorrhages, the motor sensory loss may exceed the weakness. Moreover, computerized tomography has shown that small thalamic hemorrhages may cause aphasia when on the left and hemi-inattention when on the right. [Figures C-11](#) and [C-12](#) show a large putamenal and a small thalamic hemorrhage, respectively.

Pontine hemorrhage, unless quite small, usually causes coma (by disrupting the reticular activating system) and quadriplegia (by transecting the corticospinal tracts). Eye movements, spontaneous or reflex (eg, to ice water in either external auditory canal) are absent, and pupils are pinpoint in size, perhaps in part from transection of descending sympathetic pathways and in part from destruction of reticular inhibitory mechanisms on the Edinger-Westphal nucleus of the midbrain. Pupillary light reactivity, however, is usually preserved, for the pathway subserving this reflex, from the retina to midbrain, is intact. Respirations may be irregular, presumably because of reticular formation involvement. These strokes are nearly always fatal.

Cerebellar hemorrhage, which tends to occur in the region of the dentate nucleus, typically causes a sudden inability to stand or walk (*astasia-abasia*), with ipsilateral limb ataxia. There may be ipsilateral abducens palsy, or horizontal gaze palsy, or facial weakness, presumably from pontine compression. Long-tract motor and sensory signs, however, are usually absent. As swelling increases, further brain stem damage may cause coma, ophthalmoplegia, miosis, and irregular respiration, with fatal outcome.

Figure C-11 CT scan showing hemorrhage (white area) in the putamen. (Courtesy of Dr. Allan J. Schwartz.)

The Rupture of Saccular Aneurysms Causes Subarachnoid Hemorrhage

Congenital saccular aneurysms (not to be confused with hypertensive Charcot-Bouchard microaneurysms) are most often found at the junction of the anterior communicating artery with an anterior cerebral artery, at the junction of a posterior communicating artery with an internal carotid artery, and at the first bifurcation of a middle cerebral artery in the sylvian fissure. Each aneurysm, upon rupture, tends to cause not only sudden severe headache but also a characteristic syndrome. By producing a hematoma directly over the oculomotor nerve as it traverses the base of the brain, a ruptured posterior communicating artery aneurysm often causes ipsilateral pupillary dilation with loss of light reactivity. A middle cerebral artery aneurysm may, by either hematoma or secondary infarction, cause a clinical picture resembling that of middle cerebral artery occlusion. After rupture of an anterior communicating artery aneurysm, there may be no focal signs but only decreased alertness or behavioral changes.

Figure C-12 CT scan showing thalamic hemorrhage. Hematoma is the white area surrounded by a darker zone of edema or infarction. (Courtesy of Dr. Allan J. Schwartz.)

P.1316

Posterior fossa aneurysms most often occur at the rostral bifurcation of the basilar artery or at the origin of the posterior inferior cerebellar artery. They cause a variety of cranial nerve and brain stem signs. Rupture of an aneurysm at any site may cause abrupt coma; the reason is uncertain but may be related to sudden increased intracranial pressure and functional disruption of vital pontomedullary structures.

Stroke Alters the Vascular Physiology of the Brain

After a stroke, cerebral blood flow and cerebrovascular responses to changes in blood pressure or arterial gases are altered. The term *luxury perfusion* refers to the frequent appearance of hyperemia relative to demand after brain infarction. Red venous blood may be seen draining infarcts (reflecting decreased oxygen extraction), and regional cerebral blood flow may or may not be absolutely increased. In addition, there may be vasomotor paralysis with loss of autoregulation to blood pressure changes and then blunted responses to alterations in arterial O₂ or CO₂. This kind of physiological abnormality occurs both within and around ischemic lesions.

In such patients CO₂ (or other cerebral vasodilators) may produce a paradoxical response, increasing cerebral blood flow in brain regions distant from the infarct without affecting the vessels around the lesion. Blood may therefore be shunted from ischemic to normal brain (*intracerebral steal*). In contrast, cerebral vasoconstrictors, by decreasing cerebral blood flow in normal brain without affecting the vessels of ischemic brain, may shunt blood into the area of ischemia or infarction (*inverse intracerebral steal*).

There is controversy about the frequency of these phenomena. Hyperperfusion is not invariable in infarcted brain, and it may coexist with adjacent hypoperfusion with increased oxygen extraction. Similarly, intracerebral steal, while probably most frequent with very large infarcts, is quite unpredictable (particularly in duration) in any single patient. It is also not clear whether increasing cerebral blood flow to infarcted or ischemic areas improves matters by increasing oxygen delivery and the removal of tissue-damaging metabolites or makes matters worse by increasing edema, mass effect, and anastomotic compromise.

Appendix D

Consciousness and the Neurobiology of the Twenty-First Century

With the demise of behaviorism and the development of computers in the middle of the twentieth century, consciousness became increasingly interesting as a phenomenon for possible scientific analysis. As we enter the twenty-first century, discussion of consciousness amongst neuroscientists as well as philosophers has become popular, with a large number of papers, books, seminars, and even a journal (*Journal of Consciousness Studies*) devoted to the subject. The purpose of this appendix is to provide a guide to the most relevant literature about consciousness. As discussed in [Chapter 20](#), we predict that cognitive neuroscientists will soon be designing and carrying out experiments to explain various aspects of the phenomenon. It would therefore be useful for the readers of this text to become familiar with the defining concepts.

Early Ideas About Consciousness Were Dualistic

Although the ancient Greek philosophers, notably Plato (circa 427–347 BC) and Aristotle (384–322 BC), developed important ideas about the nature of mind and soul (*psyche*), it is convenient to date modern discussions of consciousness to René Descartes (1596–1650). To arrive at certainty, Descartes discarded all ideas about which he could not be sure, and concluded that he could be absolutely certain only that he was a thinking being: *cogito, ergo sum*. Thus the only thing he could be certain of was the awareness of his own thoughts. Modern philosophers describe this introspective view of consciousness as a drama taking place in a personal Cartesian theater.

The British empiricists John Locke (1632–1704) and George Berkeley (1685–1753) and the Prussian philosopher Immanuel Kant (1724–1804), while contributing enormously to understanding the relationship between the external world and how we know it (epistemology), added very little to Descartes's basic concept of consciousness. They clearly assumed that the substance of mind is different from the substance of brain or of any other physical organ. This presumption, called dualism, was taken for granted in all accounts of consciousness until the nineteenth century. While these philosophers provided quite specific descriptions of consciousness, they were not concerned with explaining the way in which it worked. Thus no clear idea was offered about how the mental or spiritual component interacts with physical matter to result in mind and consciousness.

The Modern View of Consciousness Arose in the Nineteenth Century

The possibility of a physical explanation of consciousness became evident during the mid-nineteenth century with the rise of experimental psychology (Wilhelm Wundt [1832–1920]) and psychophysics (Gustav Fechner [1801–1887]; see [Chapter 21](#)), which presumed that

P.1318

mental activity correlates with distinct physical states (*psychophysical parallelism*). In 1890, William James (1842–1910) summarized the accomplishments of experimental psychology in his influential textbook *The Principles of Psychology*, and defined consciousness as a continuous stream that, although accessible only to the subject experiencing it, might be experimentally approached by analyzing its several functions. Thus the stream of consciousness is a continuous activity of the brain that involves attention, intentionality, and self-awareness. Self-awareness includes both perception per se and the awareness of experiencing perceptions, often referred to as “qualia.”

Modern Thinking About Consciousness Is Materialistic

Most neuroscientists and philosophers now take for granted that all biological phenomena, including consciousness, are properties of matter. This physicalist stance breaks with the tradition of dualism stemming from ancient Greek philosophy. The break with the tradition that mind and consciousness arise from a mysterious interaction of spirit with body actually focused the problem of consciousness for the twentieth century neuroscientist. Philosophically disposed against dualism, we are obliged to find a solution to the problem in terms of nerve cells and neural circuits.

Is the problem of consciousness real, however? Some philosophers and many neuroscientists believe that consciousness is an illusion. This viewpoint is an example of radical functionalism, crudely illustrated by the assertion that mind and consciousness is to the brain as walking is to the legs. Patricia Churchland makes the argument that “electrical current in a wire is not caused by moving electrons; it is moving electrons. Genes are not caused by chunks of base pairs in DNA; they are chunks of base pairs.” This point of view, called “eliminative materialism,” is magisterially explicated in Daniel Dennett's *Consciousness Explained*.

Although the field of artificial intelligence has greatly influenced cognitive neuroscience, John Searle argues that consciousness cannot be reduced to a machine that can think, a physical computer with mind as a software program and consciousness as an emergent property. He maintains that the mind is not analogous to software being processed by the hardware of the brain. He argues that programs consist entirely of a set rules, no matter how complex, is not sufficient for semantics. Searle pleads for a scientific study of consciousness, rather than a denial of its evident existence.

Certain neurological disorders have cast some light on the problem of consciousness, as they have on other aspects of brain function as the aphasias added to our understanding of language. Especially influential is the phenomenon of blindsight as studied by Lawrence Weiskrantz and his colleagues at Oxford. Patients with lesions of the primary visual cortex (V1) are blind; but when forced to make a choice on the basis of what is shown before their eyes, they can make decisions almost as if they can see. Nevertheless, these patients insist that they cannot see. Thus, they perceive but are not conscious of perceiving. Martha Farah has reviewed these curious disorders—blindsight, prosopagnosia, and neglect—and their relevance to consciousness.

Two serious theoretical explanations derived from the known properties of neurons and neural circuits have been offered. Francis Crick and Christof Koch proposed that consciousness is an integration of neural activity similar in mechanism to the binding of different aspects of sensation that occurs to produce a unified perception. Like binding, consciousness would also depend on the synchronous firing of cortical neurons at frequencies around 40 Hz. Gerald Edelman has proposed that consciousness results from several crucial functions of brain activity: memory, learning, distinguishing self from nonself, and most important, reentry—the recursive comparison of information by different brain regions. Giulio Tononi and Edelman suggest that this re-entry mechanism is localized in circuits of the thalamocortical system.

Can Consciousness Be Explained?

In a classic paper, Thomas Nagel argued that consciousness is first-person specific and unlike any other natural phenomenon. Because of its inherently subjective character, it poses a unique problem for scientific analysis. Colin McGinn took this argument a step further. Even though a materialist, McGinn believes that the human mind lacks the cognitive ability to understand the nature of consciousness, just as monkeys cannot understand particle physics. We agree that the problem of consciousness is difficult, perhaps the most difficult one that neuroscience has to face. As Crick and Koch and many others presume, consciousness must have a neural correlate. We are optimistic that future cognitive

P.1319

neural scientists will identify the neurons involved and characterize the mechanisms by which consciousness is produced.

Symbols

C	Capacitance (measured in farads).
C_{in}	Total input capacitance of a cell.
C_m	Capacitance per unit length of membrane cylinder.
C_m	Specific capacitance of a unit area of membrane (measured in $F \cdot cm^{-2}$).
E	Equilibrium (or nernst) potential of an ion species, e.g., E_{Na} , or reversal potential for current through an ion channel.
F	Faraday's constant (9.5×10^4 coulombs per mole).
G	Conductance (measured in siemens).
g	Conductance of a population of ion channels to one or more ion species, e.g., g_{Na} .
g_l	Resting (leakage) conductance; total conductance of a population of resting (leakage) ion channels.
I	Current (measured in amperes). The flow of charge per unit time, $\Delta Q/\Delta t$. Ohm's law, $I = V \cdot G$, states that current flowing through a conductor (G) is directly proportional to the potential difference (V) imposed across it.
I_c	Capacitive current; that changes the charge distribution on the lipid bilayer.
I_i	Ionic current; the resistive current that flows through ion channels.
I_l	Leakage current; the current flowing through a population of resting ion channels.
I_m	Total current crossing the cell membrane.
i	Current flowing through a single ion channel.
Q	Excess positive or negative charge on each side of a capacitor (measured in coulombs).
R	Gas constant ($1.99 \text{ cal} \cdot ^\circ K^{-1} \cdot \text{mol}^{-1}$).
R	Resistance (measured in ohms). The reciprocal of conductance, $1/G$.
R_{in}	Total input resistance of a cell.
R_m	Specific resistance of a unit area of membrane (measured in $\Omega \cdot cm^2$).
r	Resistance of a single ion channel.
r_a	Axial resistance of the cytoplasmic core of an axon, per unit length (measured in Ω/cm).
r_m	Membrane resistance, per unit length (measured in $\Omega \cdot cm$).
V_m	Membrane potential, $V_m = Q/C_m$ (measured in volts).
V_r	Resting membrane potential.
V_t	Threshold of membrane potential above which the neuron generates an action potential.
V_{in}	Potential on the inside of the cell membrane.
V_{out}	Potential on the outside of the cell membrane.
Z	Valence.
γ	Conductance of a single ion channel, e.g., γ_{Na} .
λ	Cell membrane length constant (typical values 0.1–1.0 mm). $\lambda = \sqrt{r_m/r_a}$.
τ	Cell membrane time constant; the product of resistance and capacitance of the membrane (typical values 1–20 ms). $\tau = R_m \cdot C_m$.

Units of Measurement

A	Ampere, measure of electric current (SI base unit). One ampere of current represents the movement of 1 coulomb of charge per second.
Å	Ångström, measure of length (10^{-10} m, non-SI unit).
C	Coulomb, measure of quantity of electricity, electric charge (expressed in SI base units $s \cdot A$).
F	Farad, measure of capacitance (expressed in SI base units $m^2 \cdot kg^{-1} \cdot s^4 \cdot A^2$).
Hz	Hertz, measure of frequency (expressed in S^{-1}).
M	Molar, measure of concentration of a solution (mole of solute per liter of solution).
mol	Mole, measure of amount of substance (SI base unit).
mol wt	Molecular weight.
S	Siemens, measure of conductance (expressed in SI base units $m^{-2} \cdot kg^{-1} \cdot S^3 \cdot A^2$).
V	Volt, measure of electric potential, electromotive force (expressed in SI base units $m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$). One volt is the energy required to move 1 coulomb a distance of 1 meter against a force of 1 newton. Measurements in cells are in the range of millivolts (mV).
Ω	Ohm, measure of electric resistance (expressed in SI base units $m^2 \cdot kg \cdot s^{-3} \cdot A^{-2}$).

ACPD See trans-(1S, 3R)-1-amino-1,3-cyclopentanedicarboxylic acid
ACTH See Adrenocorticotrophic hormone

Actin
in axon growth cone filopodia [1071](#) [1073](#)
filaments
as tracks for molecular motors in cell [75](#)
overlap with myosin filaments affects number of muscle fiber cross bridges [681-682](#)
in microfilaments [74](#)
motors, myosins [75](#)
movement by faster component of slow axonal transport [103](#)
muscle contraction [679](#)
in muscle fibers [677](#) [678](#)

Actin-binding proteins
movement by faster component of slow axonal transport [103](#)
network with actin filaments [74](#)

Action
internal cellular representation required for [381-403](#) See also Movement
selection, in lateral premotor areas [774-777](#)
sensory information for, role of cerebrotocerebellum [845-848](#)

Action potential [21](#) [28](#) [30](#) [126](#)
abolishes balance of ion fluxes that gives rise to resting membrane potential [132](#)
all-or-none behavior [21](#) [31](#) [158](#)
amplitude
boosted by nodes of Ranvier [148](#) [148](#)
in presynaptic cell [253](#)
reduced by lower external concentration of sodium ions [151](#)
and amount Ca²⁺ that flows into presynaptic terminal [256](#)
and density of voltage-sensitive sodium channels [30](#)
and ionic conductance [151](#)
central neuron, role of summation [227](#)
changes in membrane potential during [105](#)
characteristics [31](#)
compound [146](#) [299](#)
conducted at different rates by afferent fibers of different receptors [444](#) [447](#)
conversion of end-plate potential into at neuromuscular junction [190](#)
density of Na⁺ channels and velocity of [160](#)
difficulty for electrically coupled cells to fire [180](#)
effect of
axial resistance and membrane capacitance on rate of spread of depolarization [147-148](#)
Ca²⁺ influx during [159](#)
slowing down conduction of [148](#)
electrotonic conduction role in
propagation [145](#)
events following [157](#)
factors limiting duration [157](#)
first intracellular recording [23](#)
frequency of conveys information [31](#)
generation [29-30](#)
flow of ions through voltage-gated channels [150-158](#)
ligand-gated channel [196](#)
sequential opening of voltage-gated Na⁺ and K⁺ channels [158](#)
how do they give rise to meaning [398](#)
importance of rapid propagation [147](#)
increase of ion conduction across cell membrane during [150-151](#)
increased permeability for K⁺ in falling phase [151](#)
inhibited by inhibitory synaptic potentials in motor neuron [209](#)
initiated by integration of many EPSPs in motor neuron [209](#)
initiation [169](#)
large- and small-diameter motor neurons [686](#)
membrane permeability to Na⁺ during [133](#)
membrane potential approaches Na⁺ equilibrium potential [132](#)
message of determined by neural pathway [31](#)
motor units [685](#)

muscle fiber [676](#) [681](#)
factor in amount of active force [682](#)
number of conveys information [31](#)
opens Ca⁺ channels in nerve terminal at chemical synapse [183](#)
passive conduction of depolarization along axon and propagation of [146](#)
passive electrical properties of neuron influence speed of conduction [140](#)
presynaptic, effect of tetrodotoxin [253](#)
propagation in sensory fibers and perception of pain [473](#)
properties affecting velocity of propagation [147–148](#)
reconstruction from properties of Na⁺ and K⁺ channels [155–158](#)
in reflex [32](#)
regeneration [22](#)
regulation of calcium influx during modulates amount of neurotransmitter released [274–276](#)
repolarization at nodes of Ranvier [160](#)
saltatory conduction in myelinated axon [148](#)
selectivity of ion channels for Na⁺ during [107](#)
sensory nerves
frequency of encodes stimulus intensity [421–23](#)
sensory nerves, series of conveys sensory message to brain [421](#)
sequence of events [156–158](#)
by skin mechanoreceptors in response to vibration [437](#)
termination by repolarization of membrane [132](#)
train of [32](#)
triggered at axon hillock in myelinated axon [148](#)
waveform [146](#)

Action tremor [849](#)

Activation gate, Na⁺ channels [155](#)

Active fixation system, eye [784](#)

P.1323

Active state, ion channels [114](#)

Active zone [182](#) [188](#) [189](#) [1089](#)

presynaptic terminal, all-or-none transmitter release [261](#)

secretory machinery of neuron [183](#)

Activity-dependent synaptic modification, mediated by NMDA receptor [213](#)

Actomyosin, role in muscle contraction [75](#)

Acute intermittent porphyria, chronic neuropathy [702](#)

Acute organic brain syndrome [901](#)

Adams, Paul [241](#)

Adaptation

hair cells [619–620](#) [621](#)

movement, role of primary motor cortex [764–770](#)

prism glasses, adjustment of eye-hand coordination during [847](#)

sensory neurons [424](#) [424–425](#)

vestibulo-ocular reflex [825–828](#)

Adaptive adjustment, vestibulo-ocular reflex, hypotheses of [826–827](#)

Addiction, opioid peptides [489](#)

Addictive states [998–1013](#)

Adduction, eye movement [785](#)

muscles involved [787](#)

Adenosine

extracellular actions [970](#)

hyponogenic properties [943](#)

neurotransmitter [285](#)

Adenosine monophosphate (AMP), role in sensitization [1250–1251](#)

Adenosine triphosphate (ATP)

as chemical intermediary for pain [442](#)

converted into mechanical energy in myosin head of muscle fiber [678](#)

co-release [294](#)

extracellular actions [970](#)

hydrolysis, setup of initial concentration gradients and maintenance [129](#)

muscle contraction [679](#)

as neurotransmitter [285](#)

receptors

structure [220](#)

transmitter-gated ion channel [222](#)

required for

movement of protein through nuclear pores [93](#)

transfer of polypeptides into endoplasmic reticulum [94](#)

role in

anterograde transport to axon [101](#)

conjugation of ubiquitin [93](#)

sensitivity of ion channel gating to [114](#)

-ubiquitin-proteasome pathway, selective and regulated proteolysis of cytosolic proteins [93](#)

Adenylyl cyclase

in activity-dependent facilitation [1252](#)

role in sensitization [1250–1251](#)

type III, in olfactory signal transduction [629](#) [629](#)

Adequate stimulus [414](#)

Adhesion molecules [1078](#)

also promote neurite outgrowth [1074–1075](#) [1076](#)

cell-surface, effect of endocytosis on [97–98](#)

guidance cues for axon growth cone guidance [1071](#)

organization of presynaptic differentiation [1100](#)

Adolescents, pattern of sleep [943](#)

ADP, muscle contraction [679](#)

Adrenal gland, enlargement of in patients with unipolar depression [1220](#)

Adrenaline See Epinephrine

Adrenergic [280](#)

Adrenergic cell groups in medulla and pons [890](#) [890](#) [891–892](#)

Adrenergic receptors, types [970](#) [971](#)

Adrenocorticotrophic hormone, excessive secretion in unipolar depression [1220](#)

Adrenogenital syndrome See Congenital adrenal hyperplasia

Advanced sleep phase syndrome [954](#)
Affect [1209](#)
Affective behavior, role of serotonergic neurons [896](#)
Affective functions See Emotion
Afferent axon terminals, site of modification of reflex pathway [724](#) [725](#)
Afferent fiber groups, in peripheral nerves [444](#)
Afferent fibers
 conduct action potentials at different rates for different receptors [444](#) [447](#)
 crossing of in medulla and pons in ascending somatosensory pathway [448](#)
 distinct terminal patterns in spinal cord and medulla for somatic sensory information [447-449](#)
 nociceptive
 neurotransmitters [477](#)
 and non-nociceptive, gate-control theory of pain [482-483](#)
 terminate on neurons in dorsal horn of spinal cord [475-477](#)
Afferent neurons [25](#)
Afferent pathways, nociceptor, integrated with descending pathways by local-circuit dorsal horn interneurons [488](#)
After-potential [157](#)
Afterhyperpolarization, paroxysmal depolarizing shift, and onset of clinical seizure [919](#)
Aggregate-field view, brain function [7](#) [11](#)
Aggressive behavior See Behavior, aggressive
Aggressive behavior, and serotonergic transmission [50](#)
Aging
 behavioral changes associated with [1151](#)
 brain [1149-1161](#)
 changes in brain structure and function [1150-1151](#)
 and genomic instability [1150](#)
 molecular mechanisms [1149-1150](#)
 and number of cell doublings [1150](#)
 premature See Werner syndrome See also Alzheimer disease; Elderly
Agnosia [355](#) [498](#)
 apperceptive, drawings by patient with [1235](#)
 associative, drawings by patient with [1235](#)
 produced by damage to posterior parietal lobe [392-393](#)
 types [498-499](#)
 visual [500](#)
Agraphia, acquired disorder of writing [1183-1184](#)
Agrin
 aggregation of acetylcholine receptors in postsynaptic membrane [1112](#)
 mechanism for aggregating acetylcholine receptors at synaptic sites in muscle fiber [1093](#) [1094](#)
 in postsynaptic differentiation [1098](#)
 release by nerve terminals at neuromuscular junction [1093](#) [1094](#)
 triggers clustering of acetylcholine receptors on muscle surface [1092-1094](#)
Aguayo, Albert [1112](#)
AKAP See protein kinase A attachment proteins

Arm muscles, activation by stimulation of motor cortex [758](#)
Armstrong, Clay [163](#)
Arnold, Magda [986](#)
Arnold theory, emotion [985-986](#)
Arousability, level of, evaluation of in structural coma [903-904](#)
Arousal [871-1013](#)
 basal nucleus of Meynert modulatory role in [334](#)
 behavioral, role of histaminergic neurons [896](#)
 brain stem modulatory role in [334](#)
 confusional, from non-REM sleep, dysfunctional behaviors [956](#) [958](#)
 cortical, role of cholinergic neurons [896](#)
 from sleep, disorders of [955-958](#)
 general and specific [983](#)
 influence of locus ceruleus [896](#)
 modulated by ascending projections from brain stem [896-900](#)
 promoted by
 different neural system than that of sleep [939](#)
 stimulation of posterior hypothalamus [939](#)
 role of central nucleus of amygdala [992](#)
Arousal level
 affects performance [983](#)
 influenced by reticular formation in brain stem [320](#)
Arousal system
 ascending
 components [900](#)
 damage to impairs consciousness [899-900](#)
 injuries to [897](#)
 pathways for eye movement in [904](#)
Arrestin, interaction with phosphorylated rhodopsin in phototransduction [514](#)
Arterial blood pressure, control by parasympathetic and sympathetic systems [967-968](#)
Articulatory loop, working memory [360](#) [1239](#)
Artificial intelligence [34](#)
 and consciousness [1318](#)
Ascending arousal system, components [900](#)
Ascending pathways, nociceptive information [480-482](#) [482](#)
Ascending tract of Deiter's, vestibulo-ocular reflex [811](#)
Ascending tracts, spinal cord See Dorsal column-medial lemniscal system; Lateral spinothalamic tracts; Spinocerebellar tracts
Aserinsky, Eugene [936](#) [945](#)
Aspartate, neurotransmitter in pyramidal and spiny stellate cells of primary visual cortex [533](#)
Association, cells involved in vision [502](#)
Association areas
 brain [1165](#)
 cerebral cortex [349-380](#)
 higher-order areas of cortex [349](#)
 interaction among and comprehension, cognition, and consciousness [362-363](#)
 multimodal
 in cerebral cortex [326](#)
 integrate sensory modalities and link to action [350-352](#)
 pathways to [354](#)
 principles of function [352-362](#)
Association cortex [11](#)
 damaged in transcortical motor aphasia [1180](#)
 function illustrated by prefrontal association areas [356-362](#)
Association cortexes
 and consciousness [363](#)
 and language [1175](#)
 lesions, effect on memory [1233](#)
 stores explicit memory [1233-1239](#)
Association, cells involved in vision [502](#)
Association regions, relationship to primary sensory and motor cortices [352](#)
Associational connections, neocortex [327](#)
Associative agnosia [355](#)
Associative learning [777](#)
 eyeblink reflex, role of cerebellum [849](#)
Associative visual agnosia [1236](#)
Associativity, long-term potentiation [1260](#)
Astasia-abasia, cerebellar hemorrhage [1315](#)
Astereognosis [393](#)
 after middle cerebral artery infarction [1307](#)
Asthma, as multigenic disease [55](#)
Astrocyte, structure [21](#)
 electrical stimulation and rise of intracellular Ca²⁺ in [180](#)
 functions [20](#)
 type of glial cell [20](#)
Astroglia, perivascular, source of signals that induce expression of blood-brain barrier properties in endothelial cells [1293-1294](#)
Asymbolia for pain [482](#)
Ataxia [753](#)
 cerebellar infarction [1313](#)
 cerebellar abnormality [849](#)
 diffuse hypoperfusion [1313](#)
 infarcts of medial or lateral brain stem structures [1311](#)
Ataxic [844](#)
Athetosis [861](#)
Ativan See Benzodiazepines
Atonia [896](#)

during REM sleep [938](#)

ATP See Adenosine triphosphate

ATPase, microtubule-associated, motor molecule for retrograde fast transfer [103](#)

P.1327

Atrial natriuretic peptide, neuroactive peptide [289](#)

Atropine [696](#)

Attention

- on elements in visual field and construction of visual image [502](#)
- increase in firing rate of neurons related specifically to [401](#)
- role in creating coherent visual image [504](#) See also Selective attention selective
 - limits amounts of information reaching cortex [504-505](#)
 - and spatial location [504](#)
- visual
 - brain centers involved in [505](#)
 - changes in cellular activity [566](#)
 - and conscious awareness [504-505](#)
 - controlled by parietal cortex [794](#)
 - coordination between separate visual pathways [501-504](#)
 - coordination between separate visual pathways [565-566](#)
 - linked with saccades [794](#)
 - multimodal sensory association cortex [354](#)

Attentional control system, working memory [1239](#)

Attentive process, visual perception [503](#)

Attenuation, in signal propagation [144](#)

Atypical depression [1210-1211](#)

Auditory association cortex, left, damage in Wernicke aphasia [1179](#)

Auditory cortex

- formation of tonotopic maps on neurons in [1127](#)
- language [1174](#)

Auditory information

- neural processing [601-608](#)
- processing in bat cerebral cortex [609](#)
- processing in many areas of cerebral cortex [608-610](#)

Auditory input, and processing of

- emotional information [990](#)

Auditory nerve fiber

- firing pattern [603](#)
- projections [603](#)
- tonotopic organization [597](#)

Auditory pathways

- cochlear nucleus to auditory cortex [604](#)
- tonotopic organization [601](#)

Auditory system

- components of in midbrain [322](#)
- early-warning system [610](#)
- refinement or modification of connections by sensory experience [1127](#)
- role of posterior nuclei of thalamus [343](#)

Auditory transduction, hair cells [590](#)

Auerbach's plexus See Myenteric plexus

Aura

- preceding partial seizures [913](#)
- with seizure [920](#)

Auricle, as reflector [591](#) [591](#)

Autism, genetic component [58](#)

Autocoid [281](#)

Autogenic excitation [721](#)

Autogenic inhibition [722](#)

Autoimmune diseases See Myasthenia gravis; Lambert-Eaton syndrome

Autoimmune reaction, molecular basis of in myasthenia gravis [304-306](#)

Autonomic division, peripheral nervous system [335](#)

Autonomic function

- coordinated by central autonomic network [972-978](#)
- role of
 - hypothalamus [8](#)
 - medulla oblongata [8](#)

Autonomic ganglia

- fast and slow synaptic transmission in [242](#)
- sympathetic and parasympathetic motor systems [962](#)

Autonomic motor neurons [962](#)

Autonomic nervous system [960](#)

- acts in parallel with somatic motor system [979-980](#)
- anatomical organization [962-965](#)
- compared with somatic nervous system [960](#)
- control of visceral and ocular reflexes [966-969](#)
- divisions of [961](#)
- features [980](#)
- and hypothalamus [960-981](#)
- neurotransmitters in [970](#)
- organization of motor pathways [961](#)
- pharmacology [971](#)
- receptors in and drugs that act at [971](#) See also Parasympathetic system; Sympathetic system
- sensory inputs [965-969](#)
- sympathetic and parasympathetic divisions [964](#)
 - balance between [961-962](#)
- unipolar neurons in [24](#)
- visceral sensory and motor system [961-962](#)

Autonomic neurons

- chemical transmitters in [969-970](#)
- combinatorial release of chemical mediators [980](#)
- neuropeptides in [970](#) [972](#)
- peptides released by [980](#)

- small molecular transmitters released by [980](#)
- Autonomic reflexes, slow and rapid visceral responses [966–969](#)
- Autonomic regulation, role of dopaminergic neurons [896](#)
- Autonomic responses, pathways of control [975](#)
- Autoradiography, tracing neural projections [98](#)
- Autoreceptors [281](#)
- Autoregulation, cerebral blood vessels [1305](#)
- Autosomes [38](#)

Blood oxygen level detection, use of in functional MRI [374–375](#)

Blood pressure, hypothalamic control [974](#)

Blood supply, brain [1302–1304](#)

Blood vessels, brain [1303](#)

Blood-brain barrier [1288–1295](#)
anatomy [1288–1289](#)
developmental disorder of [1295](#)
disorders of [1294–1295](#)
metabolic [1293](#)
movement of water-soluble compounds and ions across [1292](#)
role of astrocytes [20](#)
selectivity [1289–1293](#)
transport of amino acids across [1291](#)
transport properties [1290–1292](#)

Blood-cerebrospinal fluid barrier, epithelial cells of choroid plexus regulate molecular flow across [1297](#)

BMP See Bone morphogenetic proteins

Body image, role of parietal lobe [9](#)

Body maps

- cortical, modifiable by experience [388-391](#)
- orderliness of in cortex are basis of clinical neurological examinations [388](#) See also Body surface maps;
- Somatotopic map in superior colliculus [792](#)

Body representation, related to representation of visual space [402](#)

Body resource conservation, parasympathetic system of peripheral nervous system [335](#)

Body surface

- complete representation in each area of primary somatosensory cortex [389](#)
- for each submodality of sensation in primary somatosensory cortex [387-388](#)
- map of
 - multiple in somatic sensory cortex [469](#)
 - neural, maintained at each stage of information processing [342](#)
 - primary somatic cortex, variation among individuals [1274](#)
 - produced by arrangement of central axons or dorsal root ganglion neurons [340-341](#)
- representation in brain by somatotopic arrangement of sensory inputs [458-461](#)
- touch and pressure, somatic division of peripheral nervous system [335](#)
- two-point discrimination for stimuli [436](#)

Body temperature, hypothalamic control [974](#)

Body weight, set point [1002](#)

- alteration by hypothalamic lesions [1002](#) [1002](#)

Body-centered frame of reference [498](#)

Bogen, Joseph [364](#)

Bolshakov, Vadim [1264](#)

Bombesin, neuroactive peptide [289](#)

Bone morphogenetic proteins (BMP)

- and development of neuronal identity [1048-1049](#)
- neural crest cell fate [1047](#)
- neural induction [1024](#) [1024](#)
- patterning of dorsal neural tube [1025](#) [1029-1030](#)

Bonhoeffer, Friedrich [1081](#)

Bony labyrinth [802](#)

Botulinum toxin [271](#)

- A, B, and C, target SNARE proteins [270](#)

Botulism, disorder of neuromuscular transmission [307-308](#)

Bouquet cell, double, in cerebral cortex [922](#)

Bowman's glands [626](#)

Bradykinesia [861](#)

Bradykinin

- activation of nociceptors [480](#)
- as chemical intermediary for pain [442](#)
- effect on nociceptors [481](#)
- neuroactive peptide [289](#)
- and nociceptor sensitization [477-478](#)

Braille dots

- and mechanoreceptors [438](#)
- role of inhibitory interactions in reading [461](#) See also Letters, embossed

Brain

- a priori knowledge [412](#)
- activities of as biological processes [1277](#)
- adult
 - structural changes caused by gonadal hormones [1141](#)
 - transient effects of gonadal hormones [1136](#)
- aggregate-field view of function [7](#)
- aging of [1149-1161](#)
- all behavior emanates from [6](#)
- alteration of vascular physiology after stroke [1316](#)
- anatomy [9](#)
 - abnormalities in schizophrenia [1195-1196](#)
 - organization [337](#)
- areas without blood-brain barrier [1293](#)
- association areas [1165](#)
- and behavior [5-18](#)
- blood
 - oxygen level as index of activity, PET [375](#)
 - supply divided into arterial territories [1302-1304](#)
 - vessels of [1303](#)
- blood-brain barrier [1288-1295](#)
- cellular connectionism view [7](#)
- circulation [1302-1316](#)
- cognitive capabilities [349-380](#)

P.1331

- complexity of connections within [34](#)
- consciousness as function of [396](#) See also Consciousness
- coronal sections [332](#)
- damage to by prolonged seizures [927-930](#)
- death, bilateral forebrain damage [900](#)
- development [1017-1162](#) [1139](#) [1140](#)
- distinct functional regions of [7](#) [9](#)
- diverging and converging neuronal connections [26](#)
- edema, types [1299](#)
- estradiol as masculinizing hormone for sexually dimorphic characteristics [1138-1140](#)
- experience modifies [1274-1275](#)
- functional systems on one side control other side of body [324](#)
- high expression of total genetic information encoded in DNA [89](#)
- homosexual versus heterosexual [1145](#)
- hormonally dependent sexual differentiation [1134-1140](#)
- idea of distributed processing [11](#)
- individual neurons as signaling units of [7](#)

individuality of [1274-1275](#)
information conveyed by action potentials [22](#)
integrates perception produced by nerve cells wired together according to general plan [382](#)
tactile information about an object [452](#)
language-related areas [1174](#)
localization
 of complex functions [365](#)
 mental functions in specific regions [3](#)
 neural basis of language [13](#)
major modulatory systems [890-894](#) [894](#)
mass action theory of function [12](#)
mental processes represented by elementary processing operations [15-17](#)
modulatory systems influence motivation, emotion, and memory [65](#) [333-334](#)
MRI image [9](#)
network properties of functional circuits [384](#)
neural maps in create representation of outside world [33-34](#)
nonhuman primates, cellular abnormalities [1157](#)
number of neurons in [19](#)
parallel processing in [34](#) See also Parallel processing
personal space, orderly representation of studied at cellular level [384-388](#)
positron emission in [376-377](#)
rate of blood flow to [1305](#)
reconstruction of object pattern by analysis of which nerve fibers have been excited [452](#)
relationship with behavior, opposing views [6-7](#) See also names of parts of brain and pathways
separate areas activated by motion and color [552](#)
significant inhibitory input on neuron cell bodies in [224](#)
specific sex differences and control of behavior [1141-1143](#)
structural abnormalities in Alzheimer disease [1153-1155](#)
study of
 lesions that interfere with mental functioning, cognitive neural science approach [383-384](#)
 single cells in intact and behaving animals, cognitive neural science approach [383](#)
 using clinical lesions [10](#)
synaptic connections, morphological types [202](#) [212](#)
tabula rasa [411](#)
theories of development [1139](#) [1140](#)
topographical maps in [323](#)
unique modification of by experience [1274-1275](#)
Brain-derived growth factor, binding by receptor tyrosine kinases [238](#)
Brain-derived neurotrophic factor [1055](#) [1056](#)
 blocks formation of ocular dominance columns [1124](#) [1125](#)
 candidate for organization of presynaptic differentiation [1100](#)
Brain death, as result of bilateral forebrain damage [900](#)
Brain hemispheres, bilaterality, personal neglect syndrome [393-394](#)
Brain imaging techniques, and monitoring progress of psychotherapy [1275](#) [1277](#)
Brain slice
 hippocampal [918](#)
 preparation for electrophysiological studies [918](#) [918](#)
 recording from neurons in, set up [918](#)
Brain stem [320](#) [873-888](#)
 ascending projections from monoaminergic cell groups increase wakefulness and vigilance [896-897](#)
 ascending projections modulate arousal and consciousness [896-900](#)
 bilateral lesions, effects [1312-1313](#)
 blood supplied by vertebral and basilar artery branches [1309](#)
 cell groups with long projections defined by their neurotransmitters [889-896](#)
 cholinergic cell groups in [894](#) [894](#)
 circuits for repetitive rhythmic motor patterns [656](#)
 connections with central nucleus of amygdala and tests for fear and anxiety [993](#)
 cranial nerve nuclei at various levels [884](#)
 descending motor systems modulated by spinocerebellum [843-844](#)
 descending pathways initiate walking and control speed [750-751](#)
 descending pathways to spinal cord modulate sensory and motor pathways [896](#)
 differences in organization from spinal cord [885](#)
 division of central nervous system [320](#)
 dopaminergic neurons in [892](#)
 effects of damage to [871](#)
 function [8](#) [8](#) [320](#)
 identifying sites of lesions [886](#) [886](#)
 infarction, characteristic syndromes produced [1311-1312](#)
 injury locations and loss of normal reflex eye movements [905](#)
 intact, ocular reflexes characteristic [907](#)
 lateral, emergence of cranial nerves from [877](#)
 lesions in and characteristic deficits of eye movements [789](#) [792](#)
 lower, effect of injuries to [900-901](#)
 medial and lateral descending pathways [669](#)
 mediation of emotions [980](#)
 memory of adaptive learning in vestibulo-ocular reflex [828](#)
 midline, serotonergic neurons [893](#) [893](#)
 modulates
 action of spinal motor circuits [668-669](#)
 arousal and selective attention [334](#)
 sensation, movement, and consciousness [889-909](#)
 monoaminergic nuclei, abnormalities in Alzheimer disease [1153](#)
 motor areas, somatotypical organization [648](#)
 motor circuits [663](#)
 for horizontal saccades [791](#)
 motor neurons
 corticalbulbar tract is pathway for cerebral cortex action on [671](#)
 modulated by cerebral cortex [669-671](#)
 motor nuclei, in motor system [667](#)
 nuclei, contain preganglionic cells of parasympathetic nervous system [963](#)
 motor circuits for saccades [789-792](#)

ocular motor nuclei in [788](#)
organization of stereotyped behaviors [900](#)

P.1332

pathway of descending signals from and stepping [750](#)
posterior fossa, lesion, symptoms of [1309-1310](#)
raphe nuclei of, REM-off cells regulation PGO-on cells [942](#)
regions of that control sleep [941](#)
relay nuclei mediate localization of sound [606-698](#)
reticular formation in [320](#)
 coordinates reflexes and behaviors mediated by cranial nerves [885-887](#)
 at level of medulla [887](#)
 and sleep [936](#)
same developmental plan as spinal cord [883](#) See also Medulla; Pons; Reticular formation
stereotyped motor responses [873](#)
structure [873](#)
transection [739](#)
variety of reflex circuits [663](#)
vascular syndromes [1312](#)
ventral, origins of cranial nerves [876](#)

Breathing, in obstructive sleep apnea syndrome [951-952](#)

Brightness
 component function of reflectance function [578](#)
 variations in carry visual information [579](#)
 vision [572](#)

Brikmayer, Walter [862](#)

Broca aphasia [1177](#)
 after middle cerebral artery infarction [1308](#)
 characteristics [1176](#)
 difficulty understanding grammatically complex sentences [1177-1179](#)
 frontal lobe lesion [1175-1177](#)
 MRI of lesion [1177](#)
 spontaneous speech, auditory comprehension, and repetition in [1178](#)
 and working memory [1179](#)

Broca's area
 activation when words are seen [13](#)
 Brodmann's areas included [1175](#)
 and category-specific knowledge [1236](#)
 language [1174](#) [1175](#)
 and speech [10](#) [11](#)

 types [790](#)

Burst neurons, motor circuit for horizontal saccades [791](#)

Bushy cell, cochlear nucleus [605](#) [606](#)

C

C See Capacitance

C fiber

- carry information from polymodal nociceptors [474](#)
- localization of substance P in terminal of [476](#)
- memory of input [479](#)
- wind-up phenomenon [479](#)

c-fos, activation by seizures [933](#)

C-terminal recognition sequence, membrane-anchored protein in endoplasmic reticulum [96](#)

C/EBP

- activated by CREB in long-term facilitation [1254–1255](#)
- in long-term facilitation [1256–1257](#)

C1-C2 cell groups See Adrenergic cell groups

Ca²⁺/calmodulin-dependent protein kinase, role in correlated firing of pyramidal cells in hippocampus [1267](#)

Cacineurin [249](#)

Cacosmia [635](#)

Cade, John [1216](#)

Cadherin, and neurite outgrowth [1074](#) [1076](#) [1077](#)

Caenorhabditis elegans

- mechanisms for discriminating among chemicals [635–636](#)
- sequencing of genome, genes for channels [120](#)
- solitary versus social strains, singles genes and social behavior [42](#)
- study of apoptosis during development in [1058–1061](#)

Cahill, Lawrence [992](#)

Calcarine cortex, effects of infarction of posterior cerebral artery [1308](#)

Calcarine fissure [368](#)

Calcarine sulcus [324](#)

- and category-specific knowledge [1236](#)

Calcineurin, dephosphorylation and inactivation of channels [159](#)

Calcitonin gene-related peptide (CGRP)

- co-release with ACh in efferent synapses with hair cells [623](#)
- co-release with ACh [290](#) [294](#)
- effect on nociceptors [481](#)
- neuroactive peptide [289](#)
- in sympathetic neurons [972](#)

Calcitonin, neuroactive peptide [289](#)

Calcium signaling, glial networks, and

- seizure foci [919](#)

Calcium

- and axon growth cone motility [1074](#)

- causes vesicle fusion and transmitter release at chemical synapse [183](#)

P.1333

- conducted by AMPA receptor-channels [221](#)

- and cross bridge formation in muscle fibers [680–681](#)

- determinants of permeability in AMPA-type glutamate receptors [221](#)

- effect of changes in membrane potential at synaptic terminal [274](#)

- excess in Huntington disease [866](#)

- and fusion pore [264](#) [266](#)

influx

- of in long-term potentiation in mossy fiber pathway [1260](#)

- of in long-term potentiation in Schaffer collateral pathway [1260](#)

- at presynaptic nerve terminals triggers transmitter release [160](#)

- into presynaptic sensory neuron in conditioned stimulus pathway [1252](#) [1253](#)

- regulates transcription of acetylcholine receptor genes [1096](#) [1098](#)

- triggers transmitter release [255–258](#)

intracellular

- concentration, modulatory influences on gating of ion channels [159](#)

- in excitotoxicity [928](#)

- free, regulated by axo-axonic synapses on presynaptic terminals [275–276](#)

- mechanism affecting transmitter release [260–261](#)

- regulation of influx during action potential modulates amount of neurotransmitter released [274–276](#)

- second messenger in synaptic transmission [230](#)

levels of and neural activity in retina [1124](#)

and light adaptation [514](#)

mobilization of synaptic vesicles to active zone [277](#)

in nucleus reticular cells during non-REM sleep [940](#)

regulation of store of in smooth endoplasmic reticulum [71](#)

residual

- as form of cellular memory [275](#)

- effect on synaptic transmission [274](#)

retinal ganglion neurons [1121](#)

role in neuronal function [276–277](#). See also Calcium ions

Calcium-activated K⁺ channel [158](#)

Calcium/calmodulin-dependent protein kinase [226](#)

- activation [236](#)

- regulation [235](#)

Calcium binding, and refractory state of voltage-gated ion channels [115](#)

Calcium carbonate See Otoconia

Calcium gluconate, treatment

- botulism [307](#)

- Lambert-Eaton syndrome [307](#)

Calcium ions (Ca⁺)

- as blocking molecules in ion channels [112](#)

- concentration at active zone [255](#)

- control of synaptic vesicle mobilization, docking, and fusion [272](#)

- enhanced influx of and presynaptic facilitation [275–276](#)

- muscle contraction [679](#)

- NMDA receptor-channel permeable to [212](#)

- role in mechano-electrical transduction in hair cells [617](#) [620](#) [622–623](#)

role in producing contractile force of muscle fibers [678](#)

Calnexin, chaperone protein [95](#)

Calreticulin, chaperone protein [95](#)

CAM kinase II [271](#)

 stretch reflex circuit of quadriceps muscle [208](#)
 survival of neurons in and neurotrophin [1057–1058](#)
 synapse formation similar to that at neuromuscular junction [1101–1104](#)
 synapse ultrastructure [1100](#)
 synaptic connections compared with neuromuscular junction [207](#)
 synaptic transmission [207–228](#)
 three major axes of [321](#)
 zones of contrasting activity [427](#)

Central neuron
 contain little laminin and low amounts of trophic molecules [1110](#)
 cytoplasmic proteins mediate clustering of receptors at synapses [1104](#)
 integrates excitatory and inhibitory signals into single response [222–223](#)
 myelin inhibits regeneration of axons [1110](#)
 neurotransmitter receptors cluster at synapses [1102–1103](#)
 pre- and postsynaptic membrane linked by macromolecular complexes at synapse [1105](#)
 receive excitatory and inhibitory inputs [207](#) [209](#) See also Central nervous system; Spinal neurons
 synapses
 on dendritic spines often excitatory [224–225](#)
 grouped according to function [223–226](#)
 synaptic cleft compared with that at neuromuscular junction [1103–1104](#)
 variety of inputs mediated by different neurotransmitter types [1103](#)

Central nucleus, amygdala
 connections with hypothalamic and brain stem areas and tests for fear and anxiety [993](#)
 lesions [992](#)
 projections [992](#)

Central pain [481](#)

Central pain syndrome, stroke [484](#)

Central pattern generator [754](#)
characteristics [744](#)
neurons in [744](#)
postinhibitory rebound in [744](#)
spinal cord, methods of revealing [743](#)
Central sensitization [479](#)

Cerebellar flocculus, neural integration of velocity signal in saccade [790](#)

P.1335

Cerebellar glomeruli [835](#)
Cerebellar hemisphere, projections to contralateral red nucleus and motor cortex [842](#)
Cerebellar nuclei, somatotopic organization [843](#)
Cerebellar peduncles [877](#)
cerebellum [833](#)
cranial nerve nuclei at level of [884](#)
Cerebellum [9](#) [320](#) [324](#) [332](#) [367](#) [761](#) [832-852](#)
afferent inputs [835-839](#)
anterior lobe lesions, affect anticipatory postural control [821](#) [821](#)
basic circuit of [837](#) [837](#)
blood supplied by vertebral and basilar artery branches [1309](#)
effect of thiamine deficiency on [850](#)
elimination of synapses after birth [1103](#)
fine-tuning of locomotor pattern [753](#)
folia [834](#)
function [7](#) [8](#) [8](#) [322](#)
functional regions [833-835](#)
hemorrhage, effects [1315](#)
increased blood flow in cocaine craving [1008](#)
infarction, effects [1313](#)
influence on motor systems [832](#)
influences cortical and brain stem motor systems [663-665](#)
inputs
to motor cortex [761](#)
and outputs [835](#)
intermediate, lesion of [850](#)
lateral hemispheres, input from cerebral cortex [845](#)
lesions [795](#)
affect limb movement [843](#)
effect on motor learning [848-849](#)
in right hemisphere [849](#)
lobes of [834](#)
and mental operations [850](#)
in motor learning [848-849](#) [850](#)
in motor system [667](#)
and movement
anticipatory actions [850](#)
internal feedback signals compared with external feedback signals [850](#)
nuclei [833](#)
organization [832](#)
regions of [832](#) [833](#)
required for adaptive postural control [820-821](#)
right lateral and medial, and category-specific knowledge [1236](#)
role in
adapting vestibulo-ocular control [825-828](#)
control of smooth pursuit [795-796](#)
implicit memory [1243](#)
signs and symptoms of diseases [849-850](#) [849](#)
tracts connecting to brain stem [833](#)
Cerebral aqueduct [367](#)
Cerebral arteries See Anterior cerebral artery; Middle cerebral artery; Posterior cerebral artery
Cerebral blood flow, correlation of increases with cocaine craving [1008](#)
Cerebral blood vessels, unique physiological responses [1305-1306](#)
Cerebral cortex [320](#)
acts on brain stem motor neurons through corticobulbar tract [671](#)
affective aspects of language in right hemisphere [14-15](#)
areas dedicated to processing of visual information [499](#)
anatomy [9](#) [324](#)
in ascending arousal system [900](#)
and ascending pathway of nociceptive information [480-482](#) [482](#)
association areas of [349-380](#)
associative capabilities, anatomical basis [331](#)
auditory information
in bats [609](#)
processed in many areas of [608-610](#)
auditory regions [591](#)
basal ganglia parallel circuits link with thalamus [857-861](#)
Brodmann's areas [12](#)
cell types in [922](#)
of cerebral hemispheres [322](#)
chromatic channels in [581-582](#)

and cognitive functioning [9-13 324-329](#)
columnar organization and pattern of neuronal connections in different layers [458](#)
control of saccades [792-795](#)
cytoarchitectonic characterization [11](#)
descending motor systems modulated by spinocerebellum [843-844](#)
dominance of left hemisphere [10](#)
establishment of neuronal layers in [1049](#)
evaluative component of emotion [985](#)
eye movements [797](#)
four lobes of [325](#)
functional regions [325-326 351](#)
 experimental localization [12](#)
generation and migration of neurons in [1050-1051](#)
highest level of information processing in [344-346](#)
inhibition mediated by GAB A [923](#)
injuries to and study of function of association areas [351 353](#)
input to lateral hemispheres of cerebellum [845](#)
interactions among areas to produce visual image [505](#)
intrinsic connections [457](#)
language areas, experimental confirmation [12-13](#)
layers of neurons in [326](#)
levels of electrical activity [897](#)
location for unimodal and multimodal association areas to communicate regarding sensory signals [382](#)
mediation of feelings [980](#)
modulates action of brain stem and spinal cord motor neurons [669-671](#)
motor areas of [756 758](#)
 somatotopic organization [757](#)
 somatotypical organization [648](#)
motor centers [648](#)
neuronal cell fate controlled by timing of cell differentiation [1049-1051](#)
neuronal cell types [329-331](#)
neurons defined by receptive fields and modalities [454-456](#)
neurotransmitters in cells of [922](#)
nonuniformity of layers in [327](#)
organization of [9-10 327](#)
PET identification of regions involved in language processing [14](#)
plane of division of progenitor cells influences fate [1052](#)
processing of
 olfactory information in several areas [633](#)
 pain [481-482](#)
 sensory information [345](#)
prominence of particular cell layers [328](#)
pyramidal neurons of have more extensive dendritic trees than spinal motor neurons [85](#)
regional differentiation [1036-1037](#)
regional properties during development [1038](#)
relay of taste information to [642-644](#)
role in
 cognition, history [10-13](#)
 control of smooth pursuit [795-796](#) See also Cortex; Neocortex; specific regions
sensory illusion of pain in [484 484](#)
sensory information from unimodal areas converges in multimodal areas [354-355](#)
sensory modalities conveyed to in ascending pathways [449](#)
separate operations in each hemisphere [16](#)
specialized regions [337](#)
specific regions control specific functions [6](#)
structure [8](#)
summated activity of as consciousness [897](#)
synapses eliminated after birth [1103](#)
synaptic inhibition [922](#)
time course of K⁺ concentration [1291](#)
topography of neurofibrillary tangles and senile plaques in Alzheimer disease [1153](#)

P.1336

translation of peripheral signals into specific feelings [985](#)
transmission of taste information from taste buds [642](#)
two pathways for visual processing centers [501](#)
use of extracellular recording to create three-dimensional functional maps [454](#)
vestibular projection, perception of rotation and vertical orientation [813](#)
visual information, local changes in blood flow by PET in processing [378](#)
vision processing, different areas make different contributions [497-500](#)

Cerebral hemispheres [9](#)

blood supply [1302 1304](#)
consciousness and sensory processing streams not distributed symmetrically in [363-365](#)

test of independent function in split-brain patient [365](#)
Wada test for distinguishing dominance [364](#)

Cerebral penduncle [346](#)

Cerebral ventricles, increase in volume causes hydrocephalus [1299-1300](#)

Cerebrocerebellum [834](#)

cognitive functions [846-848](#)
lesions, disrupt motor planning and prolong reaction time [846](#)
part of feedback circuit regulating cortical motor programs [845-846](#)
perceptual and cognitive functions [845](#)

planning movement and evaluating sensory information for action [845-848](#)

Cerebrospinal fluid

- alteration of composition in disease [1297-1298](#)
- comparison with serum [1296](#)
- distribution [1294](#)
- functions [1295-1299](#)
- increased intracranial pressure [1298-1299](#) [1298](#)
- transport within arachnoid villi [1295](#) [1296](#)
- ventricular organization [1288-1301](#)

Cerebrovascular accident *See* Stroke

Cerebrovascular disease

- cause of dementia [1314](#) *See also* Aneurysm; Hemorrhage; Infarction; Occlusion; Stroke

Cerebrum, arterial areas [1303](#)

Cervical flexure [1021](#) [1022](#)

Cervical region, spinal cord [338-340](#) [339](#)

Cervical ventral roots [876](#)

Cervicocollic reflex, stabilizes head relative to trunk [822](#)

Cervicospinal reflexes, collaboration with vestibulospinal reflexes to maintain postural stability [823-824](#) [823](#)

Cervicothalamic tract, ascending pathway for nociceptive information [480-482](#)

cGMP *See* Cyclic guanosine monophosphate

CGRP *See* Calcitonin gene related peptide

Ch1-Ch6 cell groups *See* Cholinergic cell groups

Chandelier cells [331](#)

- in cerebral cortex [922](#)
- GABA-ergic interneuron [329](#)

Chang, C.C. [300](#)

Changeux, Jean-Pierre [197](#) [300](#)

Channel-receptors, pore properties [220-221](#)

Channels *See* Gap-junction channel; Ion channels

Chaperones

- folding of proteins [103](#)
- import of proteins into mitochondria [93](#)
- role in
 - protein folding [91-92](#)
 - protein glycosylation in endoplasmic reticulum [95](#)

Charcot-Bouchard microaneurysms [1315](#)

Charcot-Marie-Tooth disease [710](#)

- chronic neuropathy [702](#)
- demyelination results from mutation in connexin 32 gene in Schwann cell [182](#)
- duplication of PMP22 gene causes [83-84](#)
- gene duplication in chromosome 17 [84](#)
- genetic defects in [709](#)
- nerve biopsies [84](#)
- phenotype [84](#)

Chemical coding, combinatorial release of chemical mediators by autonomic neurons [980](#)

Chemical driving force

- contribution to current flow [133](#)
- and flux of ion across cell membrane [131](#)
- ions [128](#)

Chemical ligands, effect on ion channel gating [114](#)

Chemical messengers

- as metabolites [295](#)
- histochemical detection within neurons [292-293](#)
- pheromones [633-634](#) *See also* Neurotransmitters

Chemical receptors [416](#)

Chemical senses [625-647](#)

Chemical signals, carry information [125](#)

Chemical synapses, plasticity of [34](#)

Chemical transmission, diseases of at nerve-muscle synapse [298-309](#)

Chemical transmitters

- bind to postsynaptic receptors [183-185](#)
- common biochemical features of receptors for [185](#)
- criteria for [280-281](#)
- different among neurons [33](#)

Chemoattractant molecule, guidance cue for axon growth cone guidance [1071](#)

Chemoreceptors

- nociceptors as [442](#)
- transduction of stimulus energy into neural activity requires intracellular second messengers [417](#)

Chemorepulsion, guidance cue for axon growth cone guidance [1071](#)

Chemosensory information, vertebrate and invertebrate strategies for processing [635-636](#)

Chemosensory receptors, in viscera [443-444](#)

Chemospecificity hypothesis, axon target recognition [1065-1066](#)

Chemotaxis, and axon growth [1078](#) [1080](#)

Cheyne-Stokes respiration, in coma [902-903](#)

Chiaroscuro, depth perception [558](#)

Childhood absence seizure, neuronal cell activity during [922-923](#)

Children

- confusional arousals in [956](#)
- organized dreams in [945](#)
- pattern of sleep [943](#)
- spontaneous development of language in [1171-1172](#)

Chimeric mice [49](#)

Chloride channels, gene family [119](#)

Chloride ions (Cl⁻)

- distribution [138](#)
- distribution across
 - cell membrane [128](#)
 - neuronal cell membrane at rest [128](#)
- GABA- and glycine-gated channels that conduct, mediate inhibitory synaptic action [214-219](#)
- gradient controlled by chloride transporter [132](#)
- ion channels selective for and inhibitory actions at chemical synapses [216](#)

nerve cells permeable to at rest [129](#)
passive distribution [131–132](#)
 across cell membrane [131](#)
resting ion channels in nerve cells selective for, in addition to Na⁺ and K⁺ ions [129–131](#)
role in generalized anxiety disorder [1222–1223](#) [1223](#)
secondary active transport [132](#)
selectivity of anion-selective channels for [111](#)

Chloride pathway, included in equivalent circuit model [137](#)
Chloride transporter, integral membrane protein controlling Cl⁻ gradient [132](#)
Chlorporthixene, structure [1198](#)

Chlorpromazine
 blocks dopamine receptors [1199](#)
 structure [1198](#)
 treatment, schizophrenia [1197](#)

Choice effect, voluntary movement [661](#)

Cholecystokinin
 effect on feeding [1004](#)
 neuroactive peptide [289](#)

Cholinergic [280](#)
Cholinergic cell groups, in brain stem and forebrain [894](#) [894](#)
Cholinergic neurons
 destroyed in Alzheimer disease [1154](#)
 in midbrain and basal forebrain [896](#)

Cholinergic system, basal forebrain, target for treatment of Alzheimer disease [1158](#)

Chomsky, Naom [382](#) [1171](#) [1173](#)

Chopper cell, cochlear nucleus [605](#) [606](#)
Chopper response, cochlear nucleus [606](#)

Chorda tympani fibers, hamster, response profiles [643](#)

Chorda tympani nerve (VII)
 innervation of taste buds [637](#) [643](#)
 taste information pathway [642](#)

Chordin, neural induction [1024](#)

Chorea [861](#)
 basal ganglia-thalamocortical circuit in [860–861](#) See *also* Huntington chorea

Choroid plexus
 epithelial cells regulate molecular flow across blood-CSF barrier [1297](#)
 secretes cerebrospinal fluid [1295–1297](#)

Chromatic aberration [580–581](#)

Chromatolytic reaction, after axotomy [1108](#)

Chromatolysis, after axotomy [1109](#)

Chromosomes [37](#) [38](#)
 human, map at metaphase [39](#) See *also* X chromosome
 sex [38](#)
 store genetic information [37–38](#)

Chronic granulomatous disease, molecular genetics of [705](#)

Chronic insufficient sleep syndrome [953–954](#)

Chronic neuropathies [702](#)

Chronic peripheral neuropathy, neurogenic disease of peripheral nerve [701](#)

Chronic sensorimotor polyneuropathy, muscle fiber distribution in [698](#)

Churchland, Patricia [398](#) [1318](#)

Ciliary ganglion [964](#)

Ciliary neurotrophic factor, candidate for organization of presynaptic differentiation [1100](#)

Cingulate bundle [893](#)

Cingulate cortex
 of cerebral cortex [325](#)
 and emotion [992–994](#)
 in hallucinations in schizophrenia [1190](#)
 infralimbic area, pathway of sensory information [974](#)
 mediation of feelings [980](#)
 storage of emotional memory [991](#)

Cingulate gyrus [324](#) [325](#) [367](#) [369](#)
 evaluative component of emotion [985](#)
 in limbic lobe [986](#) [987](#)
 perception of feeling and emotion [988](#)
 role in processing pain [481–482](#)

Cingulate motor areas [760](#)

Cingulate sulcus [324](#)

Cingulum [987](#)

Circadian clock
 features of [44](#)
 in flies [44](#)

Circadian cycle, disturbance of in unipolar depression [1220](#)

Circadian pacemaker neurons, resetting [937](#)

Circadian rhythm
 disturbed in insomnia [954–955](#)
 in elderly [955](#)
 flies, molecular polymorphisms in period gene [42](#)
 for homeostatic functions [1007](#)
 in mammals [45](#)
 role of period gene in flies [45](#)
 and sleep [937](#) [946](#)
 regulation by suprachiasmatic nucleus of hypothalamus [322](#)

Circle of Willis [1303](#)
 overlapping blood supply in brain [1304](#)

Circuit
 analysis, rules for [1282–1284](#) See *also* Electrical equivalent circuit model
 with capacitor [1285](#)
 with resistor and capacitor
 in parallel [1285–1286](#)
 in series [1285](#)

Circularvection [828](#)

destabilizing effect [829](#)

Circulation, brain [1302-1304](#)

Circumvallate papillae, on tongue [636 637](#)

Circumventricular organs [975](#)

- absence of blood-brain barrier [1293](#)

Cis -9, 10-Octadecenoamide, hypnogenic properties [943](#)

11-Cis-retinol [573](#)

Cisterna magna [367](#)

Cisternae, Golgi complex [96-97](#)

CK See Creatinine kinase

Clapham, David [248](#)

Classical conditioning

- association of two stimuli [1240-1242](#)
- associative learning [1240](#)
- capacity of conditioned stimulus to produce conditioned response [1241](#)
- gill-withdrawal reflex in *Aplysia* [1252-1253 1253](#)
- long-term storage of implicit memory [1254-1259](#)
- presynaptic facilitation of synaptic transmission [1252](#)
- timing of stimuli is critical [1252](#)

Clathrin

- coat
 - generation of transport vesicles [96](#)
 - mediates endocytosis of synaptic vesicles [99](#)
- coated vesicles, in endocytic traffic [98](#)
- movement by faster component of slow axonal transport [103](#)
- pits coated with [273](#)
- role in recycling of synaptic vesicles [269](#)

Claude syndrome, midbrain infarction [1312](#)

Clastrum [333 855](#)

- and visual attention [505](#)

Climbing fibers

- activity produces long-lasting effect on synaptic efficacy of parallel fibers [840-841](#)
- cerebellar afferent input [835-839 836 837](#)
- encoding of peripheral and descending information [839-840](#)
- induction of long-term depression [840](#)
- system, compared with mossy and parallel fiber systems [838](#)

Clinical neurological examinations, reliance on orderliness of cortical maps of body [388](#)

Clock mutation, mice, regulation of circadian rhythm [45](#)

Clock protein, circadian rhythm [45](#)

Clonazepam See Benzodiazepines

Clonic phase, partial seizure [913](#)

Clonidine, treatment, post-traumatic stress disorder [1222](#)

Clostridial neurotoxins, SNARE proteins as target of [270](#)

Clozapine

- opening of
 - Cl⁻ channels [219](#)
 - voltage-gated Na⁺ channels [132](#)
- presynaptic
 - terminal, regulates neurotransmitter release [253-255](#)
 - and transmitter release [253](#)
 - and release of neurotrophic factors in central nervous system [1124](#)
 - in sensory neuron, caused by serotonin [244](#)

Depolarizing currents, transmitted by electrical synapses [178](#)

Depolarizing receptor potential, compared to excitatory postsynaptic potential [416](#)

Depression [1209-1226](#)

- abnormality in function of subgenual region of frontal cortex [1212-1213](#)
- bipolar, symptoms [1211](#) See also Bipolar mood disorder and corticobasal ganglia-thalamocortical circuits, 866
- drugs effective in treatment act on serotonergic and noradrenergic pathways [1216](#)
- eye movement [785](#)
- genetically determined defects in chemical synaptic transmission [1224](#)
- major, polygenic nature [1212](#)
- and panic attacks [1222](#)
- role of serotonin and possibly norepinephrine [283](#)
- sleep disturbances in [948](#)
- treatment [1213-1220](#)
- unipolar
 - clinical features [1210](#)
 - disturbance of circadian cycle in [1220](#)
 - disturbances of neuroendocrine function [1220](#)
 - exclusion criteria [1210](#)
 - functional abnormality in prefrontal cortex ventral to genu of corpus callosum [1212](#)
 - types [1210](#)

Depth

- agnosia [499](#)
- of field, role of visual cortex in focusing eyes at [561](#)
- perception [548-571](#)
 - far-field, monocular cues [558](#) [559](#)
 - near-field, stereoscopic cues [560](#)
- processing in cerebral cortex [497-500](#)
- vision, monocular cues and binocular disparity [558-562](#)

Dermatomal maps [445](#)

Dermatomes [447](#)

- distribution [445](#)
- pain [445](#)
- spinal, correspond to cortical map of body [458](#)

drug-replacement therapy for Parkinson disease [865](#)

level

- in basal ganglia decreased in Parkinson disease [864](#)
- released in brain increased by drugs of abuse [1010-1012](#)

neurons releasing [979 980](#)

and phosphorylation in the neuron [249](#)

receptor

- antischizophrenic drug that blocks [1205](#)
- blocked by antipsychotic agents [1198 1199](#)
- D4, gene encoding, role in novelty-seeking human behavior [51](#)
- striatal output pathways [857](#)
- types [1199 1200](#)

small-molecule neurotransmitter [282](#)

synthesis and degradation [1201](#)

transporter, site of action for cocaine and amphetamines [1011](#)

Dopaminergic cell groups, in midbrain and forebrain [892-893](#)

Dopaminergic fibers, substantia nigra to striatum, effect of sectioning of feeding behavior [1003-1004](#)

Dopaminergic innervation, prefrontal association area [361](#)

Dopaminergic neurons

- in brain stem and hypothalamus [892](#)
- limbic, and novel stimuli that elicit reward [1010](#)
- in midbrain [896](#)
- in substantia nigra and corpus striatum [50](#)
- systems of [1201-1203 1203](#)

Dopaminergic pathways, mesolimbic, recruitment by drugs of abuse [1009-1012](#)

Dopaminergic synapses

- modulation of direct and indirect pathways from striatum [857](#)
- sites of action for psychoactive substances [1201](#)

Dopaminergic synaptic transmission, abnormalities in and schizophrenic symptoms [1200-1204](#)

Dopaminergic systems, treatment of schizophrenia with antipsychotic drugs acting on [1197-1200](#)

Dopaminergic tracts [1203](#)

- location [283](#)

Dormant inhibition hypothesis, temporal lobe epilepsy [931](#)

Dorsal [321](#)

Dorsal acoustic stria, auditory pathway [604](#)

Dorsal anterior insular cortex, pathway of sensory information [446](#)

Dorsal cerebellar vermis, lesions [795](#)

Dorsal column medial lemniscal system, pathway of sensory information [446](#)

Dorsal column nuclei

- pattern of excitation and inhibition in neuron of in increases spatial resolution [463](#)
- thalamus [343](#)

Dorsal column-medial lemniscal system, pathway for perception of touch and proprioception [447-448](#)

Dorsal columns

- fascicles [447-448](#)
- stimulation, relief of pain [482](#)
- transection, behavioral defects produced by [468](#)
- white matter of spinal cord [338](#)

Dorsal commissural interneurons, development [1028](#)

Dorsal extrastriate cortex [775](#)

Dorsal horn, spinal cord [319 338](#)

Dorsal lateral prefrontal cortex, motor cortex [794](#)

Dorsal longitudinal fasciculus [987](#)

Dorsal motor nucleus of vagus [881](#)

Dorsal motor vagal nucleus location and function [885](#)

- noradrenergic neurons in [890](#)
- pathway of sensory information [974](#)

Dorsal root, spinal cord [320](#)

Dorsal root ganglion [340](#)

cell

- inhibitory descending pathway, pain [486](#)
- pathway of sensory information [446](#)
- clustering of primary sensory neurons of trunk and limbs in [340](#)
- forms monosynaptic circuit with spinal motor neuron, knee-jerk stretch reflex [73](#)
- in knee jerk [26](#)
- mapping of innervation [445](#)

neurons

- central axons arranged to produce N map of body surface [340-341](#)
- functions [431](#)
- innervate viscera [444](#)
- primary afferent fiber [431](#)
- sensory neurons for modalities of somatic sensory system [430-431 431-432](#)

sensory specialization preserved in ascending pathway and central nervous system [447](#)

- topographic arrangement of skin receptors preserved in central processes of [447](#)
- rate and amount of slow axonal transport [102](#)

Dorsolateral frontal area, damaged in transcortical motor aphasia [1180](#)

Dorsolateral funiculus, inhibitory descending pathway, pain [486](#)

Dorsolateral motor nucleus [668](#)

Dorsolateral prefrontal association cortex, densely interconnected region of association cortex [362](#)

Dorsolateral prefrontal circuit, basal ganglia, role in executive functions [866](#)

P.1345

Dreaming [936-947](#)

functions of [944-945](#)

Dreams

- color versus black and white [946](#)
- influence of external stimuli on content [945-946](#)
- influence of stimulation of homeostatic system on [946](#)
- organization of [946](#)
- recall after awakening from REM and non-REM sleep [945](#)
- and REM sleep [946](#) See also Sleep
- sexual content in [946](#)
- violent enactment during sleep [956](#)

DRG cells See Dorsal root ganglion cells

Drinking

- elicited by angiotensin II [1006](#)
- regulated by tissue osmolality and vascular volume [1006-1007](#)
- signals terminating [1007](#)

Drive states [998-999](#)

Drive states, purposes [999](#)

Drosophila melanogaster

- circadian rhythm in [42](#)
- generation of mutations in [48-19](#)
- genes causing learning deficits in [1257](#)
- introduction of transgenes into [43](#)
- model for Huntington disease [865](#)
- neurogenesis in [1041-1047](#)
- short-term and long-term memory formation in [1258-1259](#)
- single genes affect behaviors in [42 44-56](#)

Drug

- addiction, features characterizing [1011-1012](#)
- addictive See Drugs of abuse; specific drug names
- binding to cell-surface receptors of nerve cells [6](#)
- blocking molecules in ion channels [112](#)
- brain uptake of and lipid solubility [1291](#)
- ion channels as site of activity [105 115](#)

Drugs of abuse

- dependence on in absence of

 - dopaminergic mechanisms [1011](#)

- increase level of dopamine released in brain [1010-1012](#)
- nucleus accumbens as target of action [1011](#)
- recruitment of mesolimbic dopaminergic pathways [1009-1012](#) See also Self-stimulation; specific drug names withdrawal symptoms, 1011-1012

Dualism, early ideas about consciousness [1317](#)

- DuBois-Reymond, Emil [6](#)

Duchenne muscular dystrophy [710](#)

- deletion of membrane protein dystrophin in [707](#)
- inherited myopathy [701 704 705](#)
- molecular genetics of [705-706](#)
- muscle fiber distribution in [698](#)
- X-linked [705](#)

Ductus reuniens [802](#)

dunce, *Drosophila* learning mutant [1257](#)

Dyes, tracing neural projection [98](#)

Dying back [732](#)

Dynamic equilibrium [817](#)

Dynamic polarization, principle of neural organization [23](#)

Dynamin

- GTPase involved in vesicle endocytosis [273](#)
- mediates endocytosis of synaptic vesicles [99](#)

Dynorphin

- amino acid sequence [487](#)
- co-release with glutamate [294](#)
- interaction with opioid receptors [485-486](#)
- precursor structure [291](#)
- striatum [856](#)
- in sympathetic neurons [972](#)

Dysarthria [700](#)

Dysdiadochokinesia, in cerebellar disease [849 849](#)

Dyskinesias [861](#)

Dyslexia, developmental [1184-1185](#)

Dysmetria [844](#)

- cerebellar abnormality [849](#)

Dysphagia [700](#)

Dysphoric [1210](#)

Dysthymia [1211](#)

Dystonia [862](#)

Dystroglycans, muscle [708](#)

Dystrophin [710](#)

- glycoproteins associated with [708](#)
- location on muscle plasma membrane [708](#)
- low levels in Becker muscular dystrophy [707](#)
- role in normal muscle [707-708](#)

 equivalent circuit [203](#)
 ion channels permeable to Na⁺ and K⁺ [191-192](#)
Endocrine function, role of hypothalamus [8](#)
Endocrine myopathies, acquired myopathic disease [701](#)
Endocrine regulation, role of dopaminergic neurons [896](#)
Endocrine system, control of by hypothalamus [978-979](#)

Endocytic pathway, vesicular traffic from plasmalemma [103](#)

Endocytic vesicles, neuron [69](#)

Endocytosis

- bulk [98](#)
- clathrin-mediated [98](#)
- functions of [97-99](#)
- receptor-mediated [98](#)
- role of synaptotagmin [273](#)
- study of with capacitance measurements [266](#)
- types in endothelial cells [1289](#)

Endoderm [1021](#)

- formation of neural tube [1020](#)

Endogenous bursters, in central pattern generator [744](#)

Endogenous depression See Melancholic depression Endolymph, 802-803

- semicircular canals [805](#)

Endolymphatic hydrops, and Meniere disease [807-808](#)

Endolymphatic sac [802](#)

Endolymphatic spaces, vestibular labyrinth, edema of and Meniere disease [807-808](#)

Endoplasmic reticulum

- attachment of polysomes to [90-91](#)
- element, retrograde transport to cell body [102](#)
- resident proteins [94](#)
- role in protein synthesis [91](#)
- rough [90-91](#)
- smooth, anterograde transport to axon [101](#)
- synthesis and modification of secretory and vacuolar apparatus proteins [94-96](#)

Endosomes

- in endocytosis [98](#)
- neuron [68 69](#)
- retrograde transport to cell body [102](#)
- vesicles that deliver lysosomal enzymes to [97](#)

Endothelial cells

- brain-derived signals induce expression of blood-brain barrier properties [1293-1294](#)
- brain microvessels

 - specialized properties of and blood-brain barrier [1288-1289](#)
 - tight junctions [1290](#)
 - ultrastructural features [1289](#)

Energy metabolism, hypothalamic control [975](#)

Engel, Andrew [306](#)

engrailed 1 and 2, expression in developing midbrain [1035](#)

Enkephalins

- interaction with opioid receptors [485-486](#)
- precursor structure [291](#)

Enterhinal cortex, olfactory information processing [633](#)

Enteric division, autonomic nervous system [961](#)

Enteric nervous system

- autonomous nature [964-965](#)
- effect of disruption of connections to central nervous system [965](#)

Enteric neuron, develops from neural crest cells [1047](#)

Enteric system, autonomic division of peripheral nervous system [335](#)

Entorhinal area, abnormalities in Alzheimer disease [1153](#)

Entorhinal cortex [332 1232](#)

- processing memory for explicit memory storage [1232](#)

Environment

- interaction with genes [36](#)
- prediction of events in, and learning [1240-1242](#)
- shapes consequence of mutation [39](#)
- shared and nonshared components [41-42](#)
- spatial, hippocampus contains cognitive map of [1264](#)

Enzymatic pathways

- calcium-dependent, activation during synaptic transmission [274](#)
- for degradation of neurotransmitter in synaptic cleft [294](#)

Eph kinases

- binding of ephrins to is inhibitory signal to developing axons [1079](#)
- required for formation of retinotopic map in optic tectum [1083-1084](#)
- segmental expression in hindbrain patterning [1033](#)

Ephaptic transmission [703](#)

Ephrins

- binding to eph kinases is inhibitory signal to developing axons [1079](#)
- gradients of as guidance molecules for axonal growth cones [1082](#)
- provide inhibitory signal to axon growth cones [1081](#)
- required for formation of retinotopic map in optic tectum [1083-1084](#)
- role in axon growth cone guidance [1081](#)
- segmental expression in hindbrain patterning [1033](#)

Epicritic sensations [431 431-32](#)

Epidermal growth factor, binding by receptor tyrosine kinases [238](#)

Epilepsies, classification [911-913 911](#)

Epilepsy [910-935 913](#)

- altered cortical development as cause [931](#)
- chronic temporal lobe, ictal and interictal phenomena in [15](#)
- destructive lesions of [15](#)
- development after discrete cortical injury [931](#)
- electroencephalogram in patient with [916](#)
- factors leading to are unsolved mystery [930-933](#)
- first surgical treatment for [911](#)
- generalized

 - GABA-ergic inhibition in [923](#)
 - production by penicillin in cats [923](#) See also Convulsions, Benign familial neonatal

- hippocampal size in patients with [927](#)
- irritative lesions of [15](#)
- Jacksonian march [388](#)
- nocturnal frontal lobe, mutation of nicotinic acetylcholine receptor subunit in [931](#) See also Temporal lobe

surgical treatment [925-927](#)
precursor structure [291](#)
syndrome [913](#)

- genetic, inheritance patterns [931](#)

temporal lobe

- dormant inhibition hypothesis [931](#)
- EEG rhythms at beginning of seizure [929](#)
- GABA-ergic inhibition reduced in animal models [931](#)
- hippocampal atrophy in [929](#)

PET scan of patient with [929](#)

- surgical treatment [928-929](#)

Epinephrine

- biosynthesis and structure [283](#)
- biosynthetic enzymes [281](#)
- small-molecule neurotransmitter [283](#)

Episodic ataxia, caused by point mutation in delayed-rectifier, voltage-gated K⁺ channel [169](#)
Episodic knowledge See Knowledge, episodic

erbB kinases, regulated by neuroregulin to stimulate acetylcholine receptor synthesis [1094](#)
Error signal [656](#) [1000](#)
Escape responses [180](#)
Escher, Maurits [493](#) [493](#)
Esterase, degradation of neurotransmitter in synaptic cleft [294](#)
Estradiol

- masculinizing hormone for sexually dimorphic brain characteristics [1138-1140](#)
- prevents apoptotic cell death in sexually dimorphic nucleus of the preoptic area [1140](#)
- stimulates neurite growth [1139-1140](#) [1139](#)

Estrogen

- and brain development [1139](#) [1140](#) [1141-1143](#)
- exposure of developing brain to [1146](#)
- sequestered by alpha-fetoprotein in postnatal rat [1138](#)

Estrous cycle, effect on density of synapses on dendritic spines in striatum radiatum [1142](#)
État lacunaire, after occlusion of penetrating arteries [1309](#)
Ethology [6](#)
Ethosuximide, blocks absence seizures [924](#)
Eustachian tube [591](#) [591](#)
Everts, Ed [383](#)
Everts, Edward [764](#) [792](#)
Evoked otoacoustical emission, cochlea [600](#)
Evoked potentials

- cortical, use in mapping neural representations of body surface [385-387](#)
- map of
 - cortical responses to tactile stimulation [386](#)
 - neural representation of specific areas of body in somatosensory cortex [385](#)

Evolutionary conservation of molecular mechanisms of memory [1247](#)

- in voltage-gated ion channels [166](#)

Excitability, properties of vary between regions of neuron [159-160](#)
Excitation

- competitive effect with inhibition in nerve cell [226](#)
- inhibitory networks restrict spread to sharpen spatial resolution [461-163](#)

Excitatory postsynaptic potential (EPSP) in central nervous system [226](#)

- characteristics of due to opening and closing of channels [240](#)
- compared to depolarizing receptor potential [416](#)
- current flowing during, calculation [202](#)
- determination of value [191](#)
- and end-plate current [191](#)
- effect of inhibitory synaptic input on [217](#)
- fast, principal synaptic pathways for ganglionic transmission in sympathetic and parasympathetic systems [970](#)
- fast versus slow [242](#)
- in motor neuron [209](#)
- mediated by glutamate-gated channels conducting Na⁺ and K⁺ [212-214](#)
- NMDA-type glutamate receptor-channel contribution to [215](#)
- pattern of electrical current flow [914](#) [914](#)
- polarity in surface
 - electroencephalogram [915](#)
- reversal potential for [210-211](#)
- slow, in postganglionic neurons [970](#)

Excitatory synaptic current, in large-diameter and small-diameter motor neurons [686](#)
Excitotoxicity [928](#)

- activation of AMPA receptors [930](#)
- role of apoptosis in [928](#)
- specific to certain neurons [930](#)
- underlies seizure-related brain damage [927-930](#)

Executive functions, role of dorsolateral prefrontal circuit of basal ganglia [866](#)
Exoendocytosis, synaptic vesicle membranes [97](#)
Exocentric coordinate system [817](#)
Exocrine glands, controlled by autonomic nervous system [960](#)
Exocytosis [31](#) [182D](#)

receptors

-channel, structure [220](#)

clustering at synaptic sites on central neurons [1102–1103](#)

role in generalized anxiety disorder [1222](#)

structure [219](#)

transmitter in reticular nucleus of thalamus [344](#)

Gamma-globulin, in cerebrospinal fluid [1297–1298](#)

Ganglionic reflexes, mechanism [968](#)

Ganglion, firing rate is measure of light intensity differences illuminating center and surround [519](#)

P.1352

Ganglion cell [508](#)

bipolar cells convey cone signals to [520–521](#)

cochlea [601](#)

conveys output of retina [517](#)

density of in fovea [528](#)

detection of contrasts and rapid changes [519–520](#)

from hemiretinas, make divergent choices at optic chiasm [1066](#)

in phototransduction [521](#)

process different aspects of visual image [520](#)

receive signals from photoreceptors through interneurons [520–521](#)

retinal

centrally organized receptive fields [529](#) [582](#)

parallel pathways for processing visual information [517](#)

response to contrast in their receptive fields [516](#) See also Amacrine cells; Bipolar cells; Horizontal cells

structure [515](#)

structure of receptive field [517–518](#)

Ganglionic transmission, fast and slow synaptic potentials in [970](#)

Gap junction channels, mechanism of gating in [113](#)

GAP-43 See Growth-associated protein of 43kDa

Gap-junctions [176](#)
Gap-junction channels [176](#)
 conditions for closing [180](#)
 connect communicating cells at electrical synapse [178-179](#)
 flow of inorganic cations and anions through [180](#)
 hemichannels [178](#)
 role in glial function and disease [180-182](#)
 structure [118-119](#) [118](#)
 three-dimensional model [179](#)
Gastrin, neuroactive peptide [289](#) [290](#)
Gastrocnemius muscle, histochemical analysis for muscle diseases [698](#) See *also* Stretch reflex
Gastrointestinal reflexes, mechanism [968](#)
Gate-control theory, pain [482-483](#) [486](#)
Gated ion channels [125](#) See *also* Gating; Ion channels
Gating [112](#)
 charge [162](#)
 controlled by redistribution of charges within voltage-gated Na⁺ channels [162](#)
current [162](#)
 currents, measure changes in charge distribution associated with Na⁺ channel activation [163](#)
 glutamate receptors [213](#)
 ion channels, molecular mechanisms [112-113](#)
 modification when phosphorylation state is changed by a protein kinase [159](#)
 modulation by calcium [159](#)
 Na⁺ channel [155](#)
 springs, hair cells [617](#)
 through ionotropic versus metabotropic receptors [240](#)
 voltage-sensitive ion channels, influence of cytoplasmic factors [159](#)
Gaze
 combined head and eye movements [796-797](#)
 control of [782-800](#)
 movements, controlled by many of same centers that control saccades [797](#)
 paralysis, ocular reflexes characteristic [907](#)
 system, components [783](#)
Gazzaniga, Michael [16](#) [364](#) [365](#)
GDNF See Glial-derived neurotrophic factor
Gelineau, Jean-Baptiste [949](#)
Gene expression [37-38](#)
 alteration of in mental disorders [1276](#) [1277](#)
 altered by second messenger mediation of phosphorylation of transcriptional proteins [249-250](#)
 changes in induced by psychotherapy [1275](#) [1277](#)
 in consolidation of long-term implicit memory [1256-1257](#)
Gene knockout
 methods of restricting [1268-1270](#) [1269-1270](#)
 techniques [51](#)
Gene transcription, changes in as longest-lasting form of synaptic transmission [251](#)
General anosmia [635](#)
Generalized anxiety disorder
 alterations in synaptic function [1224](#)
 role of GABA-A receptor system [1224](#)
 symptoms [1222](#)
Generalized seizures See Seizures, generalized
Genes
 and behavior [36-62](#)
 expression [37-38](#)
 housekeeping functions [59](#)
 interaction with environment [36](#) See *also* specific names
 segregation pattern [38](#)
 single
 affect behaviors in flies [42](#) [44-6](#)
 defects in can affect complex behaviors in mice [47](#) [50](#)
 in human behavioral traits [51-55](#)
 specialized functions [59](#)
Genetic anticipation [54](#)
Genetic component, mental disorders, alteration of gene expression [1276](#)
Genetic diversity, origins of [40](#)
Genetic factors, in homosexuality [1145-1146](#)
Genetic linkage analysis
 detection of coinheritance of mutated disease gene and genetic marker [53](#)
 study of schizophrenia and bipolar affective disorder [59](#)
Genetic markers, and genetic polymorphisms [52-53](#)
Genetic polymorphism [38](#)
 and genetic markers [52-53](#)
Genetic predisposition
 panic attacks [1221](#)
 schizophrenia [1193-1195](#)
Genetic risk factors, Alzheimer disease [1156-1157](#)
Geniculate ganglion
 innervation of taste buds [643](#)
 taste information pathway [642](#)
Geniculocortical fibers, branching patterns
 after eye closure and in normal development [1121](#)
Genital ducts, sexual differentiation [1133](#)
Genitalia, external, sexual differentiation depends on hormones produced by testes [1132-1134](#)
Genome
 analysis, behavioral traits [59](#) [60](#)
 Caenorhabditis elegans, sequencing of genome, identification of genes for channels [120](#)
 instability, and aging [1150](#)
Genotype [38](#)
 as determinant of human behavior [40-42](#)
 relationship with phenotype [38-40](#)
Genu of seventh nerve, control of sleep [941](#)
Geocentric coordinate system [817](#)

Georgopoulos, Apostolos [765](#)
Gephyrin, and clustering of neurotransmitter receptors at central neuron synapses [1103](#) [1004](#)
Germ cells [38](#)
Geschwind, Norman [500](#)

- classical conditioning [1252-1253](#) [1253](#)
- long-term sensitization [1254-1255](#)
- sensitization in [1250-1251](#)

Gilman, AI [231](#)
P.1353

GIRK See Ion channels, G protein-regulated inward-rectifying K⁺
g₁ See Leakage conductance
Glabrous [432](#)
Glaucoma, disturbance of color vision [585](#)
gli gene, effects of mutation in [1029](#)
Glial cell

- cell fate controlled by local signaling [1047-1049](#)
- classes of [1049](#)
- differentiation in central nervous system [1049](#)
- ensheathment, after axotomy [1109](#)
- function within seizure foci [919](#)
- generation of from neural crest [1047-1048](#)
- growth factor control diversification [1048](#)
- network [180](#)
- produce myelin sheath around signal-conducting axons [85](#)
- radial [20](#)
- resting channel selective for K⁺ [128](#)
- resting ion channels selective for K⁺ [128-129](#)
- role of gap junctions in [180-182](#)
- secreted factor direct differentiation of neural crest cells into [1048-1049](#) See *also* Astrocytes; Oligodendrocytes as support cells in nervous system, 20-21
- types [20-21](#) [21](#)

Glial growth factor

- and development of neuronal identity [1049](#)
- neural crest cell fate [1047](#)

Glial-derived neurotrophic factor, neurotrophic receptor [1057](#)
Global aphasia

- after middle cerebral artery infarction [1308](#)
- brain areas damaged in [1181](#)
- characteristics [1176](#)
- no ability to comprehend language, formulate speech, and repeat sentences [1181](#)
- spontaneous speech, auditory comprehension, and repetition in [1178](#)

Global motion, object, computation by brain [556](#)
Globose nucleus, cerebellum [833](#) [833](#)
Globus pallidus [325](#) [332](#) [347](#) [761](#)

- basal ganglia [331](#) [855](#) [855](#)
- left, reduction in blood flow in schizophrenia [1195](#)
- surgical intervention at in Parkinson disease [863](#) [863](#)

Glomerulus olfactory bulb neurons [630](#) [631](#)

- structure [631](#)

Glossopharyngeal cranial nerve (IX)

- in developing hindbrain [1031](#)
- functions [879-880](#)
 - and dysfunction [874-875](#)
- and homeostasis [965](#)
- innervation of taste buds [637](#) [643](#)
- origin at brain stem [876](#) [877](#)
- taste information pathway [642](#)

Glove and stocking pattern, paresthesias [702](#)
Glucagon, neuroactive peptide [289](#)
Glucose

- concentration in cerebrospinal fluid [1297-1298](#)
- pattern of consumption in brain measured with PET [376-377](#)
- transporter isotype-1, hexose transporter of blood-brain barrier [1290](#)

Glut1 See Glucose transporter isotype-1
Glutamate

- biosynthesis and structure [284-285](#)
- biosynthetic enzymes [281](#)
- channel gated by and conducting Na⁺ and K⁺ mediate EPSP [212-214](#)
- comparison of single-channel current activated by with GABA- and glycine-activated [218](#)
- co-release with dynorphin [294](#)
- enhanced release of during long-term potentiation [1262](#)
- excitatory transmitter in central nervous system [226](#)

excitotoxicity [214](#) [866](#)

- late response of NMDA-type channel to [213](#)

in mossy fiber pathway [1260](#)

- neuronal cell death induced by in Huntington disease [865-866](#)
- neurotransmitter [284-285](#)
 - in cone cells [518](#)
 - in hair cells [622](#)
 - in nociceptive afferent fibers [477](#)
 - in pyramidal and spiny stellate cells of primary visual cortex [533](#)
 - in pyramidal cells of cerebral cortex [922](#)
 - released by cochlear hair cells [601](#)
- receptors [226-227](#)
 - agonists, initiation of locomotor activity [751-752](#)
 - AMPA-type, determinants of Ca²⁺ permeability in [221](#)

classes that regulate excitatory synaptic actions in CNS neurons [213](#)
clustering at synaptic sites on central neurons [1102-1103](#)
ionotropic gating [213](#)
effect of drugs on [212](#)
types [212](#)
metabotropic
effect of drugs on [212](#)

Hydra head activator, neuroactive peptide [289](#)

Hydrencephalus [873](#)

Hydrocephalus
causes [1299-1300](#)
types [1299](#)

Hydroperoxyeicosatetraenoic acid, modulation of ion channels [238](#)

Hydrophobicity plot, identification of membrane-spanning region of ion channel [117](#)

6-Hydroxydopamine, injection into cortex surrounding principal sulcus disrupts performance of delayed-response tasks [361-362](#)

5-Hydroxytryptamine see Serotonin

Hyperalgesia [475](#)
and histamine release from mast cells [478](#)
hyperexcitability of dorsal horn neurons [479](#)
peripheral and central origins [477-479](#)

Hypercolumns [539](#) [545](#)

Hyperkplexia See Startle disease

Hyperexcitability, hippocampus and amygdala, experimental model of [931-932](#)

Hyperkalemia periodic paralysis
results from ion channel defects [123](#)
caused by point mutation in alpha-subunit of gene for voltage-gated Na⁺ channel in skeletal muscle [167](#) [169](#)

Hyperkinetic disorders [861](#) See *also* Hemiballismus; Huntington disease
underactivity in indirect pathway of basal ganglia [864](#)

Hyperphagia [1002](#)

Hyperpolarization [28](#) [126](#) [127](#) [127](#) [127](#)
after-potential [157](#)
cochlear hair cells [601](#)
decreases steady-state Ca²⁺ influx [274](#)
loss of accompanes onset of partial seizure [924](#)
membrane of cone photoreceptors after light absorption [574](#)
photoreceptor [513](#) [514-515](#)
responding to light [416](#)

Hyperpolarizing currents, transmitted by
electrical synapses [178](#)

Hyperreflexia [700](#)
following spinal cord transection [730-735](#)

Hypertonus [730](#)

Hypoglossal cranial nerve (XII)
in developing hindbrain [1031](#)
function and dysfunction [874-875](#) [800](#)
origin at brain stem [876](#) [877](#)

Hypoglossal nuclei [671](#) [881](#)
location [883](#)

Hypokalemic periodic paralysis, caused by
mutation in Ca²⁺ channels [169](#)

Hypokinetic disorders [861](#) See *also* Parkinson disease

Hypopnea
methods for documenting [949](#)
obstructive sleep apnea syndrome [952](#)

Hypoperfusion, diffuse, and ischemia or infarction [1313-1314](#)

Hyposmia [635](#)

Hypotension, cause of spinal cord infarction [1314](#)

Hypothalamic nucleus INAH-3, larger in heterosexual than in homosexual men [1145](#)

Hypothalamus [332](#) [367](#) [980](#)

- ablation experiments and temperature regulation [1001](#)
- anterior, sexual dimorphism of four interstitial nuclei [1144](#) [1142](#)
- ascending projections from monoaminergic cell groups increase wakefulness and vigilance [896-897](#) and autonomic nervous system [960-981](#)
- in autonomic response control pathway [975](#)
- connections with central nucleus of amygdala and tests for fear and anxiety [993](#)
- control of
 - endocrine responses to temperature [1001](#)
 - endocrine system [978-979](#)

I See Current

Ia afferent fibers

- distribution of action potentials distributed among spinal motor neurons [721](#)
- motor cortex reflex circuit [765](#)
- presynaptic inhibition and modulation of spinal reflexes [724](#)

Ia axons, excitatory inputs to motor neurons innervating synergist muscles [721](#)

Ia fibers, direct connections on motor neurons in stretch reflex [717](#)

Ia inhibitory interneurons [717](#)

- motor cortex reflex circuit [765](#)
- pathways of reflex action [722](#)
- spinal cord, complex excitatory and inhibitory inputs [765](#)
- stretch reflex, coordinate muscle contraction during voluntary XSmovements [717](#) [720](#)

Ia sensory fiber, response to selective activation of motor neurons [719](#)

Ib inhibitory interneurons, input from Golgi tendon organs [722-724](#)

Ic See Capacitive current

ICMS See Intracortical microstimulation, 759

Ictal phenomena [15](#)

II See Leakage current

Illusion

- apparent motion [551](#) [552](#)
- and visual perception [495](#) [495](#) [496](#) [496](#)

Image, saliency map [567](#)

Imagined space [384](#)

Imaging techniques See Magnetic resonance imaging; Positron emission tomography; Magnetoencephalography

- functional, use of to determine cognitive function [366-379](#)

Imipramine, antidepressant, structure [1213](#)

Immobilized preparations, study of stepping [738-739](#)
Immunocytochemistry, detection of chemical messengers within neurons [292](#)
Immunoglobulin superfamily cell adhesion molecules, promote neurite outgrowth [1076 1077](#)
Immunogold, detection of chemical messengers within neurons [292-293](#)
Immunohistochemistry, detection of chemical messengers within neurons [292-293](#)
Implementation system, language [1174 1175](#)
Implicit memory [1231 1231](#) See Memory, implicit
Imprinting [1128](#)
In situ hybridization, detection of chemical messengers within neurons [292](#)
Inactivation
 gate, Na⁺ channels [155](#)
 inhibitors, effect on noradrenergic neurons [1218-1219](#)
 voltage-gated channels entering refractory state after activation [114](#)
Incus [591 591 595](#)
Indirect immunofluorescence, detection of chemical messengers within neurons [292-293](#)
Individuality
 biological basis [1247-1279](#)
 biological expression of and somatotopic map produced by learning [1274-1275](#)
 unique modification of brain by experience as biological basis of [1275](#)
Inducing factor [1022](#)
Inertia, overcome by muscle force [688-689 690](#)
Infants, pattern of sleep [943](#)
Infarction
 anterior cerebral artery [1305 1308](#)
 brain stem, characteristic syndrome produced [1311-1312](#)
 caused by diffuse hypoperfusion [1313-1314](#)
 cerebellar [1313](#)
 middle cerebral artery [1305](#)
 types and symptoms [1306-1308](#)
 pons, PET scan [1311](#)
 posterior cerebral artery [1306 1308](#)
 spinal cord [1313](#)
Inferior cerebellar peduncle [833](#)
Inferior cervical ganglion [964](#)
Inferior colliculus [788 877](#)
 auditory pathway [604 608](#)
 cranial nerve nuclei at level of [884](#)
 formation of tonotopic maps on neurons in [1127](#)
 tonotopic map and layers [608](#)
 sound localization [608](#)
Inferior mesenteric ganglion [964](#)
Inferior olive, lesions, effect on motor learning [848-849](#)
Inferior parietal lobe, damage to in conduction aphasia [1180](#)
Inferior parietal lobule
 effect of damage to [355](#)
 in visual attention [354](#)
Inferior salivatory nucleus, location and function [885](#)
Inferior temporal cortex [501](#)
 cells in respond to both form and color [565](#)
 cells responding to similar features are organized into columns [565](#)
 effect of lesions in on visual system [498](#)
 effects of visual attention of cells of [565-566](#)
 face recognition [564-565](#)
 form and color [502](#)
 inputs to [564](#)
 response of one neuron to complex visual stimuli [566](#)
Inferior temporal gyrus [333](#)
Inferior temporal lobe, ventral pathway to and object vision [562-565](#)
Inferior temporal pathway
 cross talk with posterior parietal pathway [567-568](#)
 visual [500-501](#)
Inferior [321](#)
Inferotemporal cortex
 and basal ganglia, hallucinations in schizophrenia [1190 1190](#)
 explicit learning of facial identity [989](#)
Inflammation
 neurogenic [479](#)
 symptoms reproduced by substance P [478-479](#)
Information
 amount reaching cortex limited by selective attention [504-505](#)
 carried by electrical and chemical signals [125 295](#)
 cognitive, parallel and distributed processing of [349](#)
 conveyed by action potentials [22](#)
 diversity transferred in single synaptic action [295](#)
 features of conducting signal that carry [31](#)
 flow
 in primary visual cortex [533](#)
 from sensory neurons to motor neurons is divergent and convergent [79](#)
 through relay nuclei controlled by inhibitory mechanisms [427](#)
 genetic, stored in chromosomes [37-38](#)
 integration in higher cortical areas [463-468](#)
 nociceptive, ascending pathways [480-482](#)
 processing [383](#)
 functional systems for in central nervous system [323](#)
 highest level in cerebral cortex [344-346](#)

P.1359

nature of in neocortex [330](#)
rapid, ion channels tuned for [105](#)
sensory, principles of [352-362](#)
sequence in motor system reversed from that in sensory system [355-356](#)
specific areas for in cerebral cortex [325-326](#)

in thalamus [344](#)
recursive comparison by different brain regions [1318](#)
sensory
conveyed by populations of sensory neurons [416](#)
parallel processing [319](#)
processed in serial pathways [426-427](#)
somatosensory, carried by parallel and hierarchical pathways to spinal cord and brain [341](#)
steps for processing in memory [1231-1232](#)
stored, recall is not exact copy of original information [1239](#)
tactile, object, fragmented by peripheral sensors and integrated by brain [452](#)
theory, focus on cognition [313](#)
time-sensitive, carried rapidly and over long distances by transient electrical signals [125](#)
transmitted from receptors by modulation of frequency of electrical impulses [430](#)
types of storage of in memory [1228-1233](#)
visual, processing in multiple cortical areas [496-497](#)

Ingram, Vernon [867](#)

Inhibition
competitive effect with excitation in nerve cell [226](#)
feed-forward and feedback [26-27](#) [27](#)
lateral, and two-point discrimination [461](#)
reduction of EPSP [216](#)
sculpturing role [209](#) [209](#) [461](#)
and reduced output of projection neurons [461](#)

Inhibitory current, impact in postsynaptic neuron [225](#)

Inhibitory inhibition, interneurons, and central pattern generators [744](#)

Inhibitory interneurons See Interneurons, inhibitory

Inhibitory molecules, guidance cue for axon growth cone guidance [1071](#)

Inhibitory neurons, eye movement [798](#)

Inhibitory postsynaptic potential
recorded from hippocampal pyramidal cell [923](#)
polarity in surface electroencephalogram [915](#)
in postganglionic neurons [970](#)
spinal motor neurons, mechanism of [215](#) [217](#)

Inhibitory surround
cortical neuron [461](#)
seizure focus [921](#)

Inhibitory synaptic action, mediated by GAB A- and gly cine-gated channels that conduct chloride [214-219](#)

Inhibitory synaptic potential, reversal [216](#)

Ink gland, *Aplysia*, inking response mediated by electrically coupled high-threshold motor cells [180](#) [181](#)

Inner ear
bony and membranous labyrinths [802](#)
structure [592](#)
vestibular and cochlear divisions [802](#)

Inner hair cells
cochlea [596](#)
organ of Corti [596](#)

Innervation, dorsal root ganglia, mapping [445](#)

Inositol polyphosphates, second messenger in synaptic transmission [230](#)

Input component, nerve cell signaling [28-29](#)

Input signal [27](#) [30](#)

Insertional plaque, hair cells [619](#)

Insomnia [948](#) [954-955](#)
advanced sleep phase syndrome [954](#)
delayed sleep phase syndrome [954](#)
disturbed circadian rhythm in [954-955](#)

Inspiratory cramps, in coma [903](#)

Instructed-delay task [772](#)

Insula
affected in conduction aphasia [1180](#)
damaged in global aphasia [1181](#)
left, and category-specific knowledge [1236](#)
planning and coordinating articulatory movements for speech [1182](#) [1183](#)

Insular cortex [332](#)
of cerebral cortex [325](#)
language [1175](#)
lesions [482](#)
role in processing pain [481-82](#)
somatosensory cortical area [452](#)

Insulation, membrane, effect on conducting properties [144-145](#)

Insulin
euroactive peptide [289](#) [290](#)
precursor structure [291](#)

Integral membrane protein [94](#)

Integrator [1000](#)

Integrins, on axon growth cone interact with laminins in extracellular matrix [1074](#)

Intelligence, general, dissociation from language [1172](#)

Intensity, stimulus attribute conveyed by sensory systems [412](#) [413](#) [414](#)

Intention tremor [849](#)

Interblobs
primary visual cortex [549-550](#)
visual cortex [501](#)

Interdental cells, organ of Corti [598](#)

Interhemispheric fissure [368](#) [369](#)

Intercritical phenomena [15](#)

Intercritical spikes, in vitro brain slice [917](#)

Interleukin-1
hypnogenic properties [943](#)
increases temperature set point [1001](#)

Intermediolateral cell column, in autonomic response control pathway [975](#)

calcium closely related to Na⁺ channels [164-166](#)
concentration at presynaptic terminal of neuromuscular junction [259](#)
molecular bases for diversity [257](#)
-sensitive K⁺ channels [621](#) [622](#)
types [256-257](#)
and voltage-dependent K⁺, and afterhyperpolarization in paroxysmal depolarizing shift [919](#)
calcium-activated K⁺ channel [158](#)
cation-selective [110](#)
cGMP-gated during phototransduction [512](#)
in photoreceptors [511](#)
during darkness [513](#)
chimeric [117](#)
chloride
 effect of opening on EPSP [217](#)
 mechanism for inhibition of postsynaptic cell [29](#) [217](#)
 cloning and sequencing of genes for [116](#)
 combinations of and response to excitatory input [160](#)
 common ancestor for genes of Na⁺, K⁺, and Ca²⁺ channels [164-166](#)
 comparison of synaptic excitation produced by opening and closing [240](#)
 conductance and ion permeation [111-112](#)
 contribute to determination of ionic permeability properties of cell membrane [106-107](#)
 control rapid changes in membrane potential [123](#)
 current linearly related to voltage [110](#)
 current flow as nonlinear function of driving force [111-112](#)
 delayed rectifier [158](#)
 different combinations expressed [33](#)
 differing selectivities [123](#)
 direct gating [230](#)
 mediated by ionotropic receptors [184](#)
 direct modulation by G proteins [244-248](#)
 dissociation constant [112](#)
 each acting as conductor and battery in parallel [134](#)
 effect of drugs and toxins on gating [114](#)
 end-plate
 motor neuron opens to excite muscle [190](#)
 permeability to Na⁺ and K⁺ [192](#)
 evolutionary conservation of structure and function [117](#)
 factors contributing to selectivity of [163-164](#)
 families of [118](#)
 flux of ions through is passive [110-112](#)
 functional methods of study [109-110](#)
 functional properties can change over course of development [120](#) [120](#)
functional states [114](#)
G protein-regulated inward-rectifying K⁺ [248](#)
G-protein-coupled inward rectifying, activation by ACh [247](#)
GABA, role in disease [219](#)
GABA-A chloride, structural model [1223](#)
GABA-gated, recording of current [217](#)
GABA-gated Cl⁻
 activation of and presynaptic inhibition [275](#)
mediate inhibitory synaptic action [214-219](#)
opening can cause excitation in brain cells [219](#)
gap-junction, structure [118-119](#) [118](#)
gated [107](#) [125](#)
 directly or indirectly by postsynaptic receptors [185](#)
gating [112](#)
 in hair cells [617](#)
 physical models for [113](#)
 types of stimuli controlling [113](#)
glutamate-gated and conducting Na⁺ and K⁺, mediates EPSP [212-214](#)
glycine, role in disease [219](#)
glycine-gated Cl⁻, mediate inhibitory synaptic action [214-219](#)
recording of current [217](#)
gramicidin A [109](#)

P.1361

hydrophilic [70](#)
gramicidin, current varies with membrane potential in linear manner [109](#)
hydrophobicity plot to identify membrane-spanning regions of [117](#)
grouping into gene families [118-120](#)
h-type [158](#)
hair cells, opened by mechanical force [617-619](#)
indirect gating [230](#) [230](#)
mediated by metabotropic receptors [184](#)
individual acetylcholine-gated, conduct unitary current [193-194](#)
influx of Ca²⁺ alters metabolic processes in cell [123](#)
initiation of signal [65](#)
inward rectifying K⁺, structure [119](#)
inward rectifying [248](#)
ions conducted across by receptors [108](#)
length of time open [194](#)
ligand-gated [107](#) [185](#)
 acetylcholine receptor, structure [118](#) [118](#)
 ATP-activated channels, gene family [119](#)
 differences from voltage-gated channel [196](#) See also Ion channels, acetylcholine-gated

structure [118](#) [118](#) [220](#)
ligand-gates, as on-off switches [240](#)
linear nature of current flow through [112](#)
M-type K⁺ channel [159](#) [241](#)
control excitability [243](#)
M-type, outward K⁺ current and accommodation to prolonged depolarizing stimuli [243](#)
malfunctioning [105](#)
measurement of current flow with patch clamp [192–193](#)
mechanically gated [107](#)
mechanoelectrical transduction, cation-passing pores [616–617](#)
mediate electrolyte movement across blood-brain barrier [1292–1293](#)
mediation of changes in membrane potential [105](#)
methods of testing proposed structure [117–118](#)
model for selectivity for Na⁺ or K⁺ ions [106–107](#)
modification of activity [123](#)
monovalent cation-permeable [158](#)
nicotinic acetylcholine
 activation, proteins forming [201](#)
 gated, and receptor, formed by single macromolecule [197–201](#)
nonlinear relation between current and membrane potential [112](#)
number of types [119–120](#)
occlusion of [112](#)
ohmic [112](#)
open and close as result of conformational changes [112–116](#)
P region as selectivity filter [119](#)
passive potassium, as equivalent electrical circuit [134](#)
patch-clamp recording of current flow [111](#)
permeability for specific ions [138](#)
potassium
 blockade of in sour taste transduction [641](#)
 in bitter taste transduction [640](#)
 closed by cAMP-dependent protein kinase [243](#)
 increased opening following action potential [157](#)
 possible common ancestral channel [164–166](#)
 responses during long-term depolarization [156](#)
 -selective, structure solved by X-ray crystallography [120–123](#) [122](#)
 substances that block [154](#)
 study with voltage clamp technique [151–154](#)
properties [105](#) [107](#)
proposed structure of gramicidin A channel [110](#)
proteins [108](#)
and rapid informaton processing [105](#)
and resting potential [149](#)
rectifying [112](#)
regulate flow of ions across cell membrane [123](#)
regulation of [107](#)
regulatory mechanisms for amount of time channel is open and active [114](#)
relationship between structure and function [169](#)
relative proportion of types determines resting membrane potential [130](#)
resting [65](#) [107](#) [125](#)
 determination of resting membrane potential [126](#) [128](#)
 determine resting membrane potential [126–132](#)
 Na⁺, K⁺, and Cl⁻, representation by single equivalent conductance and battery [137](#)
 selective for K⁺ only in glial cells [128–129](#)
 selective for several ion species in nerve cells [129–131](#)
S-type K⁺
 activated by FMRFamide [243](#)
 activity recorded by patch-clamp technique [245–246](#)
 closed by serotonin [243](#)
 slow synaptic action mediated by FMRF amide opens those that are closed by serotonin [246](#)
selective for Na⁺, K⁺, or Cl⁻, represented by a battery in series with a conductor [134](#)
selective for Na⁺, K⁺, or Cl⁻, represented by battery in series with conductor in electrical equivalent circuit [134–135](#) [134](#)
selectivity [107](#) [108](#)
selectivity filters in [108–109](#)
selectivity for types of ions [110–112](#)
serotonin ligand-gated, in central nervous system [221–222](#)
shared characteristics [110–116](#)
short-term and long-term effects of chemical transmitter [250](#)
signaling in the nervous system [105–107](#)
site of action of drugs, poisons, and toxins [105](#)
sodium
 activation gate [155](#)
 closely related to Ca²⁺ channels [164–166](#)
 different conformations of in response to depolarization [154–155](#)
 distinct entities [160](#)
 during action potential [156–157](#)
 gating currents directly measure changes in charge distribution [163](#)
 gating relies on redistribution of net charge in S4 region [167](#)
 inactivation after end of depolarization [156](#)
 inactivation gate [155](#)
 mechanism of inactivation [163](#)
 rapid rate of turning on and off over range of membrane potentials [156](#)
 residual inactivation following action potential [157](#)
 response during long-term depolarization [156](#)
 in salty taste transduction [640](#)
 structure [164](#)
 study with voltage clamp technique [151–154](#)
 substances that block [154](#)
 and velocity of action potential [160](#)
structure [116–123](#) [116](#)
study of function [123](#)

T channel, in thalamic relay neurons [924](#)

targets of disease [123](#)

transmitter-gated

ATP receptor [222](#)

removal, effect on language in infant versus adult [1182](#)

Left inferotemporal cortex, language [1174](#)

Left midtemporal sector, damage causes difficulty recalling unique and common names [1182](#)

Left posterior inferotemporal sector, damage affects recall of words for items [1182](#)

Left prefrontal cortex
language [1174](#)
reduced blood flow in schizophrenia [1196](#)

Left superior oblique muscle, eye, symptoms of deficit [789](#)

Left superior temporal gyrus, damage to in conduction aphasia [1180](#)

Left temporal cortices, damage causes naming defects [1182](#)

Left temporal lobe
damage in Wernicke aphasia [1179-1180](#)
damages causes difficulty in recalling unique names [1182](#)
language [1174](#)

Leg movements, periodic, methods for documenting [949](#)

Lemon, Roger [769](#)

Length constant, passive membrane property of neuron [222-223](#)

Lens
chromatic aberration [580-581](#)
eye [508](#)

Lenticulostriate arteries
effects of occlusion [1309](#)
white matter and diencephalic structures [1304](#)

Leptin
control of body fat [1005-1006](#)
effect on food intake [1004](#)
gene, mutations in affect feeding behavior in mice [47](#)
protein encoded by obese gene [47](#)

P.1365

Lesions
brain, and increased intracranial pressure [1298](#)
somatic sensory cortex, produce sensory deficits [468-469](#)
spinal cord, sensory and motor signs [732-734](#)

Lethargic [901](#)

Letter memory test, brain areas of significant change in activity during [1184](#)

Letters, embossed, detailed representations by cortical neurons [464](#) [465](#) See *also* Braille dots

Leucine-enkephalin
amino acid sequence [487](#)
neuroactive peptide [289](#)

Leukemia inhibitory factor (LIF)
induction of switch from noradrenergic to cholinergic neurotransmitter phenotype [1051-1052](#)
neurotrophic receptor [1057](#)

Leukotrienes
and nociceptor sensitization [477-478](#)
sensitization of nociceptors [480](#)

Levi-Montalcini, Rita [1054](#) [1055](#) [1056](#) [1057](#)

Lewis, Ed [1032](#)

Lexical processing [13](#)

LHRH See Luteinizing hormone release hormone

Lichtman, Jeff [1101](#)

LIF See Leukemia inhibitory factor

Ligand-gated channel See Ion channels, ligand-gated

Light
absorption by visual pigments in photoreceptors [510](#)
adaptation to and calcium role [514](#)
effect on
cone photopigments [573-574](#)
membrane potential in rods and cones [509](#) See *also* Pupillary reflexes; Vision
slow adaptation of photoreceptors to changes in intensity [515-517](#)
source, visual perception [496](#) [497](#)
wavelengths and color [572](#)

Limb amputation, and use of anesthesia [479](#)

Limb kinetic apraxia [355](#)

Limb muscles, M2 response [727](#)

Limb-girdle muscle dystrophies
classification of [709](#)
inherited myopathic disease [701](#) [704](#) [705](#)
mutations of sarcoglycan genes in [707-708](#)

Limb-position sense [443](#)

Limbic association area
cerebral cortex [350](#)
function [352](#)

Limbic circuit, basal ganglia, links thalamus and cerebral cortex [858](#)

Limbic dopaminergic neurons, and behavioral activation [1009-1010](#)

Limbic lobe [325](#)
cortical representation of feeling [986-988](#)

Limbic system
beta-adrenergic mechanisms and storage of emotional events in mice [992-993](#)
components [987](#)
developing forebrain [1036](#)
interconnections of deep-lying structures [987](#) See also Amygdala

Limbic thalamo-cortical system, vulnerable in Alzheimer disease [1153](#)

Limbs
motor control and sensation mediated by spinal cord [320](#)
somatosensory information conveyed from by dorsal root ganglion neurons [431](#)
from carried to spinal cord [338-340](#)

Lindstrom, Jon [300](#)

Linear perspective
depth perception [558](#)
monocular depth cue [559](#)

Linguistics, focus on cognition [313](#)

Linkage analysis
genetic mapping strategy [56](#) See Genetic linkage analysis sensitivity to model of transmission, 57-58

Lipid bilayers
artificial characterization of current in gramicidin A channel [110](#)
study of ion channels [109](#)
planar, use in patch-clamp recording [111](#)

Lipid solubility, and brain uptake of drugs [1291](#)

Lipid-soluble substances, and blood-brain barrier [1289-1290](#)

Lisberger, Stephen [826-827](#)

Lithium salts
mechanism of action [1220 1220](#)
treatment, bipolar mood disorder [1216](#)

Livingstone, David [489](#)

Livingstone, Margaret [550](#)

Llinas, Rodolfo [255 840 924](#)

Lobes, cerebellar [322](#)

Lobotomy [993](#)

Local interneurons [329 335](#)
afferent connections within spinal cord [667](#)
functional regions [28](#)
organization in spinal cord [667](#)

Local sign [654](#)

Location, stimulus attribute conveyed by sensory systems [412 413 413](#)

Locke, John [6 411 493 1240 1317](#)

Locked-in syndrome
bilateral lesions of corticospinal tract [1313](#)
result of injury to lower brain stem [900](#)

Locomotion [737-755](#)
adaptive postural control learned during [821](#)
descending signals initiating transmitted via reticulospinal pathway [751-752](#)
initiation via descending glutaminergic pathways [752](#)
pattern generator, hypothetical [746](#)
and posture, adaptability [822](#) See also Stepping
stereotyped action [737](#)

Locomotor pattern, fine-tuning by cerebellum [753](#)

Locomotor responses, electrical stimulation of mesencephalic locomotor region [751](#)

Locus ceruleus
abnormalities in Alzheimer disease [1153](#)
in ascending arousal system [900](#)
brain stem nucleus, functions [871](#)
control of sleep [941](#)
inhibitory descending pathway, pain [486](#)
location and function [891 891 895-896](#)
noradrenergic neurons in [891 891 895-896](#)
noradrenergic pathways originating in [1215 1216](#)
ventral, lesions of in cats and dream enactment [956](#)

Locus coeruleus See Locus ceruleus

Lod score [56](#)

Loewi, Otto [175 280 966 967](#)

Lomo, Terje [1259](#)

Long-loop reflexes [727-728 728](#)

Long-loop responses [767](#)

Long-term depression (LTD)
induction by climbing fibers [840](#)
synaptic transmission, cGMP cascade role in [240](#)

Long-term potentiation (LTP) [275](#)
associative in
Schaffer collateral and perforant pathways [1260](#)
and spatial memory [1267 1272](#)
defect in and lack of NMDA receptor in hippocampus [1270-1271 1272](#)
enhanced release of glutamate [1262](#)
fine-tunes properties of place cells [1267](#)
genetic interference with [1264](#)
hippocampal, and explicit memory [1259-1272](#)
increase of neurotransmitter vesicles and receptors in [1264](#)
model for
early and late phases [1265](#)
induction [1260-1261](#)

P.1366
mossy fiber pathway of hippocampus [1258](#)
new protein synthesis during late phase [1262-1264](#)
nonassociative in mossy fiber pathway [1260](#)
phases of [1262-1264 1263](#)
reversal of deficit of in hippocampus [1273](#) See also Calcium influx

Longevity, human, trends from ancient times to present [1150](#)

Longitudinal fasciculus, left medial, vestibulo-ocular reflex [811](#)

Lorazepam See Benzodiazepines

treatment, prolonged repetitive seizures [919](#)
Lorente de No, Raphael [329](#)
Lorenz, Konrad [1128](#)
Lou Gehrig disease See Amyotrophic lateral sclerosis
Lower motor neurons [696](#)
 symptoms of disorders of [696](#)
LTD See Long-term depression
LTP See Long-term potentiation
Luciani, Luigi [849](#)
Lumbar puncture, measurement of cerebrospinal fluid pressure [1298](#)
Lumbar region, spinal cord [338-340](#) [339](#)
Luminance contrast [531](#)
 response of P and M cells [530](#)
Luria, A.R. [402](#)
Luria, Aleksander [351](#)
Luteinizing hormone, neuroactive peptide [289](#)
Luteinizing hormone release hormone, sex difference in control of release [1135](#)
Luxury perfusion [1316](#)
Lysosomes, role in protein synthesis [91](#) [93](#)

M

M cells
 attributes [581](#)
 chromatic properties [579](#)
 and image movement [580](#)
 retinal ganglion cells [501](#) [520](#)
 projections [545](#)
 sensitivity to stimuli, compared with P cells [530](#)
M cones [576](#) [577](#)
M current
 anti-accommodation effect of inhibition [242](#)
 effect of muscarine on [242](#)
M ganglion cells, projection to magnocellular layers of lateral geniculate nucleus [529](#)
M pathway
 function [545](#)
 projections [567-568](#)
 visual system [501](#) [505](#)
 functions mediated by [502](#)
M-type K⁺ channel See Ion channels, M-type K⁺
M-wave, Hoffmann reflex [731](#)
M1 response, reflex [727](#)
M2 response, reflex [727](#)
Machado-Joseph disease, type of trinucleotide repeats involved in [56](#)
MacKinnon, Rod [12](#)
MacLean, Paul [987](#) [988](#)
Macrogia, types [20](#)
Macrophage infiltration, after axotomy [1109](#)
Macula, utricle and saccule [804](#)
Maffei, Lamberto [1123](#)
MAG See Myelin-associated glycoprotein
Magnesium ions, as blocking molecules in ion channels [112](#)
Magnesium, blocks current flow in NMDA-activated channels [212](#)
Magnetic resonance [371](#)
Magnetic resonance imaging [13](#) [336](#)
 anatomical mapping of seizure foci [925](#)
 different time constants used for contrast [372](#)
 functional, physical bases [374-375](#)
 functional imaging of brain [366](#)
 functional study of visual cortex [374](#)
 image of major regions of central nervous system [367](#)
 physical basis of technique [366](#)
 scan of horizontal section of cerebral hemisphere and diencephalon [368](#)
 scan through coronal section of cerebral hemisphere and diencephalon [369](#) See *also* Functional magnetic resonance imaging
 signal produced [370-371](#)
 technique [370](#)
 three-dimensional coding of signal [373](#)
Magnetoencephalography
 imaging of somatotopic functioning of cortex [458-459](#)
 use of to construct functional maps [389](#) [390](#)
Magnification factor [529](#)
Magnocellular layers, lateral geniculate nucleus [529](#)
Magnocellular neurons, hypothalamus, secrete oxytocin and vasopressin [979](#)
Magnocellular pathway [548](#)
 continues in dorsal (parietal) pathway [549](#) [550](#)
 projections [549-552](#)
 selective inactivation in lateral geniculate nucleus [551](#)
 to visual cortex [529-532](#)
 visual system, slower conduction in people with dyslexia [1185](#)
Magnus, Rudolf [817](#)
Magoun, Horace [936](#) [939](#)
Major affective disorder, genetic component [58](#)
Major histocompatibility complex, class II
 antigen, association with narcolepsy [950](#)
 role in myasthenia gravis [304](#)
Malleus [591](#) [591](#) [595](#)
Maloney, Lawrence [577](#)
Mammals, phylogenetic variations in sleep [944](#)
Mammillary body [788](#) [987](#)
Mammillothalamic tract [987](#)
Mandibular division, trigeminal nerve [878](#)
Mangold, Hilde [1023](#)

Mania [1209-1226](#)
Manic-depressive disorder as multigenic disease [55](#) See also Bipolar mood disorder
Manic-depressive psychosis [1192](#)
MAP See Microtubule-associated proteins
MAP-1C, motor molecule for retrograde fast transfer [103](#)
MAPK See Mitogen-activated kinase
Maps See Cognitive map; Master map; Neural maps; Somatotopic map; Tonotopic map

Melancholic depression [1210](#)

Melanin, in pigment epithelium of eye [508](#)

Melanin concentrating hormone, in ascending arousal system [900](#)

Melanocyte, develops from neural crest cells [1047](#)

Melanocyte-stimulating hormone release-inhibiting factor [980](#)

Melanocyte-stimulating hormone-releasing factor, hypothalamic [980](#)

Melatonin, hypnogenic effects [943](#)

Membrane
capacitance [142-143](#)
conductance [135](#)
insulation, effect on conducting properties [144-145](#)
resistance [141](#) See *also* Cell membrane
total amount is constant in cell [269](#)

Membrane anchor, on proteins for outer leaflet of plasmalemma [96](#)

Membrane capacitance, as passive electrical property of neuron [140](#)

Membrane conductance
calculation from voltage-clamp data [155](#)
and flux of ion across cell membrane [131](#)

Membrane depolarization See Depolarization

Membrane glycoprotein, forms nicotinic ACh receptor [197](#)

Membrane potential (V_m) [125-139](#) [126](#)
analysis of changes in by Goldman equation [133](#)
change in
capacitive and resistive elements [143](#)
during action potential [105](#)
mediated by ion channels [105](#)
produced by sensory stimulus transformed into digital pulse code [421](#)
and refractory state of voltage-gated ion channels [115](#)
rods and cones [510-511](#)
as signaling mechanism in excitable cells [28](#)
at synaptic terminal affects intracellular calcium [274](#)
controlling with voltage clamp technique [152](#)
depolarization [131](#)
during light adaptation in cones [515](#)
effect of membrane capacitance on [143](#)
effect on
end-plate potential, total end-plate current, and ACh-gated single-channel current [198](#)
ion channel gating [114](#)

P.1368
equal to voltage [143](#)
generation of changes in response to stimuli [105](#)
graded changes in rods and cones responding to light [509](#)
magnitude of passive changes determined by input resistance [140-142](#)
method of recoding [127](#) [127](#)
nature of [29](#)
photoreceptor during darkness [513](#)
positive feedback cycle [151](#)
rate of change slowed by membrane capacitance [143](#)
relationship to current injected into nerve cell [141](#)
resting, calculation using equivalent circuit model [136-137](#) [136](#)
resting See Resting membrane potential
separation of charges across cell membrane [126](#)

Membrane proteins
integral, ion channel component [116](#) See *also* Bacteriorhodopsin; Membrane-spanning proteins; Transporter

Membrane recovery See Synaptic vesicles, recycling

Membrane resistance [144](#)
decrease in after opening of M-type channels [243](#)

Membrane time constant [143](#)

Membrane-soluble molecules, as neurotransmitters [295](#)

Membrane-spanning proteins
as transporter molecules [295](#)
odorant receptors [628](#)
pheromone receptors [634](#)
secondary structure [117](#) See also Rhodopsin

Membranes
artificial, study of ion channels [109](#)
pre- and postsynaptic, study with freeze-fracture technique [263](#)
synaptic, exocytosis [264](#)

Membranous labyrinth [802](#)

Memory [1227-1246](#) [1227](#)
adaptive learning in vestibulo-ocular reflex [828](#)
animals studies used [1231-1232](#)
cellular, residual calcium [275](#)
and changes in strength at synaptic connections [1254](#)

Mossy fiber pathway

- direct and indirect, bring somatosensory information to spinocerebellum [841-842](#)
- hippocampus [1257 1259](#)
- long-term potentiation of [1258](#)
- long-term potentiation in is nonassociative [1260](#)

Mossy fiber system, compared with climbing and parallel fiber systems [838](#)

Mossy fibers

- cerebellar afferent input [835-839 836 837](#)
- encoding of peripheral and descending information [839-840](#)
- reorganization in epileptic temporal lobe [933](#)

Motilin, neuroactive peptide [289](#)

Motion

- actual versus apparent [551](#)
- agnosia [499](#)
- analyzed in dorsal pathway leading to parietal cortex [522-558](#)
- areas of brain activated by [552](#)
- direction of, alteration of perception by stimulation of neurons of monkey middle temporal area [558](#)
- direction of, detection by cortical neurons [464-65](#)
- illusion of [551](#)
- illusory [829](#)
- parallax, depth perception [558](#)
- perception [548-571](#)
 - altered by lesions and microstimulation of middle temporal area [556-558](#)
 - deficits produced by damage to human extrastriate visual cortex [556](#)
 - monkey middle temporal area [556](#)
 - of in visual field [551](#)
- processing
 - in cerebral cortex [497-500](#)
 - at junction of temporal, parietal, and occipital cortices in humans [553](#)
 - in monkey middle temporal area [553](#)
 - sensitivity of cells to in middle temporal area of monkey [555](#)

Motivation

- disrupted by deletion of gene that encodes enzyme important for dopamine [50-51](#)
- influenced by modulatory systems in brain [333-334](#)
- response to internal stimuli [998](#)

Motivational states [998-1013](#)

- factors regulating [1007-1009](#)
- modeled as servo-control systems [1000](#)
- and neuronal responses in S-II [468](#)
- types [998-999](#)

Motor act, neural representation [383](#)

Motor action, anticipatory

- learning of to postural disturbances [820](#)
- postural control [830](#)

precedes postural readjustment [817-818](#) [818](#) [819](#)

Motor areas

- cerebral cortex, somatotopic organization [757](#)
- functional organization [778](#)

Motor axon

- controls aspects of postsynaptic differentiation [1098](#)
- pathway to skeletal muscles [1069](#) [1070](#)

Motor cells, survival control by change in size or activity of muscle target [1054](#) [1055](#)

Motor circuit

- horizontal saccades [791](#) See also Basal ganglia-thalamocortical motor circuit; Oculomotor circuit; Skeletomotor circuit

P.1371

Motor commands

- hierarchical organization [672](#)
- parallel processing [662](#)

Motor control, role of ventral nuclei of thalamus [342](#)

Motor cortex [345](#) [347](#)

- cell activity according to nature of sequence of movements [774](#)
- columnar arrays of neurons in [778](#)
- control of precise stepping movements in visually guided movement [752-753](#)
- cortical and subcortical inputs [671](#)
- different areas activated during finger movements [773](#)
- encodes direction of movement [769](#)
- inputs from cerebellum via the thalamus [761](#)
- language [1174](#)
- monkey
 - concentric organization [759](#)
 - major inputs [760](#)
- mosaic arrangement of muscle and joint representations in [778](#)
- neuron activity and stepping movements, visual system inputs [752](#)
- pathway of descending signals from and stepping [750](#)
- plasticity of somatotopic organization [761](#)
- projections from cerebellar hemisphere [842](#)
- reciprocal nature of connections [761](#)
- reflex circuit [765](#) See also Premotor cortex; Primary motor cortex; Supplementary motor area stimulation in awake humans [758](#)

Motor cortical cells

- code force needed to maintain a reaching trajectory [770](#)
- firing rate, direct relationship to muscle force generation [768](#)

Motor disturbances, in diseases affecting basal ganglia [853](#)

information about state of conveyed by sensory neurons [76–77](#)
involuntary [654](#)
produced by cyclical attachment and detachment of myosin heads on thin filaments [679](#)
tendons and aponeuroses store mechanical energy during [678](#)

Muscle fibers [676](#)
active force produced depends on velocity at which it changes length [682](#) [682](#)
all-or-none response [676](#)
aponeuroses transmit force to connective tissue [682](#)
central motor commands to conveyed by motor neuron [77–78](#)
contractile force depends on level, length, and velocity of activation [680–683](#)
overlap of thick and thin filaments [681](#)
cross bridges
formation depends of calcium [680–681](#)
produce contractile force [678](#)
end-plate connection with motor neuron [676](#)
force
of contraction depends on number of recruited motor neurons and firing rates [687](#)
produced by cross bridges depends on velocity of sarcomere [683](#)
motor neurons convey commands to [676](#)
myofibrils in [677](#)
neuromuscular junctions [81](#)
noncontractile components [678](#) [680](#)
number of cross bridges depends on overlap between actin and myosin filaments [681–682](#)
organization into sarcomeres and cross bridges [676–683](#)
organizes differentiation of motor nerve terminals [1098–1100](#)
total force produced, length, velocity [683](#)

Muscle force
amount held in reserve for transient use [687](#)
creates stiffness at joints [689–690](#)
to overcome inertia [688–689](#) [690](#)

Muscle movements, fine-tuning by cerebellum [322](#)

Muscle nerve, afferent fiber groups in [444](#)

Muscle signals, role in reflex [32](#)

Muscle spindles
agonist and antagonist, in motor cortex reflex circuit [765](#)
and initiation of swing phase of stepping [749](#)
extensor muscles, regulation of step cycle [748](#)
fibers [719](#)
fine-tuning by fusimotor system [725](#)
in knee jerk [26](#)

innervation [718](#)
in reflex [32](#)
sensitivity of adjusted by gamma motor neurons [734–735](#)
structure [719](#)
structure and functional behavior [718](#)
types [718](#)

Muscle tone
characteristic alterations in caused by damage to central nervous system [730–735](#)
loss of during REM sleep [943](#)
mechanism for loss during REM sleep [942](#)
modulation by medial and lateral reticulospinal pathways [896](#)

Muscle unit [676](#)

Muscles
act on more than one joint [690–693](#) [692](#)
active tension and rate of stimulation of nerve [680](#)
activity, postspike facilitation of [767](#)
antagonist [715](#)
arm and hand, activation by stimulation of motor cortex [758](#)

P.1374

classification of sensory fibers [720](#)
contraction, activation of gamma motor neurons during [726](#)
Golgi tendon organs provide information about [723](#)
produces reflexive and rhythmic movements [654–656](#)
spatial extent and force depend on stimulus intensity [715](#)
co-contraction [720](#)
complex sequence of contractions in stepping [740](#) [741](#)
coordinated patterns of contraction in spinal reflexes [715–717](#)
coordination of contractions and divergence of reflex pathways [721](#)
denervated, and density of acetylcholine receptors [1096](#)
different actions of at individual joints [687–688](#)
effects of cerebellar lesions [849–850](#)
direction and amplitude of force, correlates with activity of corticospinal axon [766](#)
ending of sensory nerve in [74](#)
excitation by motor neuron, opening of end-plate ion channels [190](#)
force generation, direct relationship to firing rate of motor cortical cells [768](#)
force in and discharge rate of Golgi tendon organs [723](#)
fused tetanus [680](#)
histochemistry to distinguish neurogenic and myopathic diseases [698](#)
intrinsic mechanical properties and force [691](#)
individual, distribution of sites controlling in primary motor cortex [759](#)
limb, M2 response [727](#)
lengthening resisted in stretch reflex [717](#)
multiarticular [690–693](#) [692](#)
postsynaptic membrane clustering of acetylcholine receptors on [1092](#)
differentiation of organized by motor nerve [1091–1098](#)
programming and adjustment of motor programs [692–693](#)
propagation of contraction effects [692](#)
proteins of cytoskeleton on surface membrane [708](#)
rapid exertion of force [689](#)
red [684](#)
in reflex [32](#)
repeated activation causes fatigue [683](#)
retrograde signals to nerve in formation of neuromuscular junction [1099](#)
role in synapse elimination [1101](#) See *also* Stretch reflex
selective activation of sensory fibers [720](#)
sequential activation of agonist and antagonist and changes in joint torque [688](#)
skeletal, during obstructive sleep apnea syndrome [953](#)
spatial and temporal control of combinations of [687](#)
spontaneously active at rest in neurogenic disease [699](#)
stretch depolarizes mechanoreceptors [415](#)
structure [675](#)
successive isometric twitches [680](#)
summation of successive isometric twitches [680](#)
surrounding joint, coordinated by inhibitory interneurons [717](#) [720–721](#)
synergist [721](#)
tonic and phasic [1107](#)
torque as product of contractile force and moment arm [688](#)
types [674](#)
transduction of electrical and chemical energy to mechanical energy [693](#)
type I and type II fibers, in [698](#) [699](#)
unfused tetanus [680](#)
white [684–685](#)

Muscular dystrophies
as myopathies [696](#) See *also* Becker muscular dystrophy; Duchenne muscular dystrophy; Facioscapulohumeral muscular dystrophy; Limb-girdle muscular dystrophy; Myotonic muscular dystrophy

Muscular dystrophy
deletion in dystrophin gene and severity of [707](#)
dystrophin-normal, mutations of sarcoglycan genes in [707–708](#)
major forms [705](#)

Musculoskeletal system [693](#)

MuSK, role in clustering of acetylcholine receptors at synaptic sites in muscle fiber [1093](#) [1094](#)

Mutation
consequence of shaped by environment [39](#)
dominant [39](#)
dominant negative [39](#)
loss of function [40](#)
frameshift [40](#)
gain of function [39](#)
generating in flies and mice [48–49](#)
method for testing proposed ion channel structure [118](#)
missense [40](#)
nonsense [40](#)

point [40](#)
recessive [40](#)
types [38-40](#)
Mutism [1182](#)
Mutual inhibition, interneurons, and central pattern generators [744](#)
Myalgia [696](#)
Myasthenia gravis
antibodies to ACh receptor produced in [201](#)
antibody binds to alpha-subunit of ACh receptor in [303-304](#)
autoimmune
disease [300](#)
reaction against ACh receptor [305](#)
therapy for [306](#)
caused by disruption in transmission at synapse [174](#)
chemical synapses as target [867](#)
congenital forms [306-307](#)
disease of chemical transmission at nerve-muscle synapse [298-309](#)
experimental autoimmune [300-301](#)
failure of transmission at neuromuscular junction [302](#)
immunological changes cause physiological abnormality [302-303](#)
major forms [298](#)
neonatal [306](#)
rate of destruction of ACh receptors [304](#)
results from antibody interference with ion channel function [123](#)
Mydriasis [788](#)
Myelencephalon, development [1021](#) [1022](#)
Myelin [188](#)
inhibitor of axon outgrowth [1111](#)
inhibits regeneration of central axons [1110](#)
production by glial cells [20](#)
protein components of [83](#)
proteolipid component of [83](#)
Myelin basic proteins, role in myelin
compaction [82](#)
Myelin debris, after axotomy [1109](#)
Myelin genes, regulation of expression in Schwann cells and oligodendrocytes [85](#)
Myelin protein zero, major protein in mature peripheral myelin [83](#)
Myelin proteins
affected in hereditary peripheral neuropathies [709](#)
defects in disrupt conduction of nerve signals [82-83](#)
Myelin sheath [22](#)
on axons of central and peripheral neurons [81](#)
degeneration of in axons of corticospinal tracts in spinal muscular atrophy [700-701](#)
Schwann cells, gap junctions enhance communication [182](#)

P.1375

sensory neurons [76-77](#)
signal-conducting axons, produced by glial cells [85](#)
Myelin-associated glycoprotein
in myelin [82-83](#)
inhibits axonal elongation [1111](#)
Myelination, axonal, effect on increasing
conduction velocity [147-148](#) [148](#)
Myenteric plexus [964-965](#) [965](#)
Myocardial infarction, referred pain in [475](#) [477](#)
Myoclonus [767](#)
Myofibril
muscle fiber [677](#)
skeletal muscle fiber [676](#)
Myofilaments [677](#)
Myogenic diseases, clinical and laboratory criteria for [696-699](#)
Myoglobinuria [696](#)
acquired myopathic disease [701](#)
Myomodulins, neuroactive peptide [289](#)
Myopathic diseases
differential diagnosis from neurogenic diseases [700](#)
effect of motor unit [697](#)
histochemical diagnosis [698](#)
laboratory criteria for diagnosis [697-699](#)
molecular genetics of [705-709](#)
Myopathies
causes of weakness in [705](#)
inherited See Glycogen storage
diseases; Muscular dystrophy Myosin in axon growth cone filopodia [1071](#) [1073](#)
form of in fast-twitch white muscles [684](#)
in hair cells [600](#)
in muscle fibers [677](#)
muscle contraction [679](#)
Myosin heads
actin-binding sites [680](#)
as actin motors [75](#)
cyclical attachment and detachment on thin filaments produces muscle contraction [679](#)
muscle fiber, ATPase converts ATP into mechanical energy [678](#)
Myosin I-beta, near stereociliary tips in hair cells [620](#)
Myotonia [696](#) [704](#)
Myotonia congenita, caused by mutation in Cr channel [169](#)
Myotonic dystrophy
inherited myopathic disease [701](#)
trinucleotide repeats in [55](#) [56](#)
Myotonic muscular dystrophy, inherited myopathy [704](#) [705](#)

 signaling at [187-206](#)

Nervous system
 classes of cells in [20-25](#)
 development [1017-1162](#)
 ectodermal [1021-1022](#)
 functional subdivisions [315](#)
 homeostatic function [871](#)
 induction of patterning [1019-1040](#)
 integrative action of [29-30](#)
 and hierarchies of motor control [648](#)
 ion channels as site of signaling in [105-107](#)
 localization of function [33](#)
 parallel distributed processing organizational principle [9](#)
 pharmacology of [6](#)
 physiological investigation of [6](#)
 predominance of multipolar neurons [24](#)
 sexual differentiation [1131-1148](#)
 structure [335](#)

Nervous tissue
 as network of discrete cells [6](#)
 and neuron doctrine history [6](#)

Netrin 1, attractant and repellent for axon growth cones [1082](#)
Netrin genes, structural similarity to *C. elegans unc-6* gene [1081](#)

Netrins
 chemoattractant factors promoting axon growth [1078-1081](#)
 mediate chemotropic responses of neurons to targets [1077](#)

Network properties, functional circuits in brain [384](#)
Networks, neural, convey information in brain [33-34](#)

Neural activity
 regulates expression of acetylcholine receptors in nonsynaptic areas [1096](#) [1096-1098](#)
 relationship to specific subjective experience [397](#) [398](#)

Neural cell adhesion molecule (N-CAM)
 candidate for organization of presynaptic differentiation [1100](#)
 promotes neurite outgrowth [1078](#)

Neural circuit
 enhancement of computing power [160](#)
 organization [314](#)

Neural crest
 classes of neurons that develop from [1047](#)
 growth factors involved in cell fate [1047](#)
 pathways of cell migration in chick embryo [1046](#)
 target-dependent differentiation of neurons in [1053](#)

Neural crest cells
 differentiation [1047-1048](#)
 neural tube [1027](#)
 secreted factors direct differentiation [1048-1049](#)

Neural gain [825](#)
Neural groove [1020](#)

Neural induction
 inhibition of bone morphogenetic protein signals [1024](#)
 pathways of, *Xenopus* [1024](#)

Neural map [323](#)
 body surface [385](#)
 in brain create representation of outside world [33-34](#)

somatotopic representation in somatosensory cortex is according to degree of innervation of portions of body [344-345](#)

survival regulated by signals from neuronal target [1052-1058](#)
study
 of functional properties with brain slice preparation [918](#)
 with imaging techniques, cognitive neural science approach [384](#)
substrates for PKA in [235-236](#)
and understanding the mind [3-4](#)
types of signals produced by [27](#)
unipolar [24 24](#)

Neuropathic pain [473](#)
Neuropathies

axon [702](#)
demyelinating [702](#)
hereditary peripheral, myelin proteins affected in [709](#)
positive and negative signs and symptoms in [703](#)

Neuropeptide Y, neuroactive peptide [289](#)
in autonomic neurons [970](#)
and food intake [47](#) [50](#)
receptor gene, conservation in mammals and *C. elegans* [42](#)
stimulation of feeding behavior [1006](#)

Neuropeptides
in autonomic neurons [970](#) [972](#)
coexistence with norepinephrine and acetylcholine in sympathetic ganglia [972](#)
histochemical detection within neurons [292-293](#)
modulatory functions [973](#)
neurotransmitter in
 nociceptive afferent fibers [477](#)
 nonpyramidal cells of cerebral cortex [922](#)

Neurophypophysis See Pituitary gland, posterior

Neurophysin, in neurons that release vasopressin and oxytocin [979](#)

Neuropilins, binding of semaphorins to repulses growing axons [1080](#)

Neuropilins, receptors for semaphorins [1081](#)

Neuropsychology, founding of [10](#)

Neuroregulin, stimulates synthesis of acetylcholine receptors [1094-1096](#) [1095](#)

Neurotensin, neuroactive peptide [289](#)

Neurotransmitters [182](#) [280](#)
act directly or indirectly on ion channels [184](#)
all-or-none release from active zones of presynaptic terminal [261](#)
amount released modulated by intracellular calcium concentration [274-276](#) [274](#)
calculation of probability of release [261](#)
in cerebral cortex cells [922](#)
chemical
 in autonomic neurons [969-970](#)
 criteria for [280-281](#)
isolation of acetylcholine [966](#)
histochemical detection within neurons [292-293](#)
concentrations [295](#)
definition of brain stem cell groups with long projections [889-898](#)
discharged from synaptic vesicles by exocytosis [262-264](#)
effects depend on type of receptor [32](#)
establishment of phenotype by signals from neuronal target [1051-1052](#)
false [286](#)
increase of vesicles and receptors in long-term potentiation [1264](#)
leakage through fusion pore [267](#)
kiss-and-run release [270](#)
membrane-soluble molecules as [295](#)
modulation of amount released [277](#)
neuroactive peptides as [286-290](#)
in nociceptive afferent fibers [477](#)
packaged in vesicles [277](#)
proteins involved in vesicular release [270-273](#)
quantal release [257-267](#)
 in fixed increments [260](#)
receptors, clustering at synapses on central neurons [1103](#)
release [253-279](#)
 contribution of K⁺ efflux [254-255](#)
 contribution of voltage-gated Na⁺ channels [254](#)
depends on presynaptic depolarization [253](#)
inhibited or facilitated by axo-axonic synapses on postsynaptic cell [276](#)
mechanism of intracellular calcium effect on [260-261](#)
by output component of signaling [31-32](#)
regulated by depolarization of presynaptic terminal [253-255](#)
from synaptic vesicles through opening of fusion pore [267](#)
through fusion pore [268](#)
triggered by calcium influx [255-258](#)
 into presynaptic terminal [256](#)
removal from synaptic cleft terminates synaptic transmission [294-295](#)
reuptake mechanisms [294-295](#) See *also* Serotonin
small-molecule [281](#)
 actively taken up into vesicles [285-286](#)
as chemical substances for signaling [281](#)
co-release with neuroactive peptides [290](#) [294](#)
compared with neuroactive peptides [290](#)
transport from
 cytosol into vesicles [287](#)
 synaptic cleft into cytosol [287](#)
storage and release by synaptic vesicles [261-267](#)
substances identified as [282-286](#)

Neurotrophic factor hypothesis [1055](#) [1055](#)

Neurotrophic factors [1056](#)
deprivation of triggers caspase activation [1060](#)
receptor interaction [1056](#) [1057](#)
release from target neurons enhanced by synchronous presynaptic activity [1123-1125](#)
secretion by target cells [1055-1056](#) [1056](#)

Neurotrophin 3 [1055](#) [1056](#)

Neurotrophin 4/5 [1055](#) [1056](#)

Neurotrophins
mechanism of action [1058](#)
modulation of formation of ocular dominance columns [1125](#)
and survival of neurons in central nervous system [1057-1058](#)

Neurturin, neurotrophin receptor [1057](#)

Newsome, William [558](#)
Newson-Davis, John [306](#)
Newton's laws of mechanics, and muscle force [689](#) [690](#)
NGF See Nerve growth factor
NI-35, inhibits axonal elongation [1111](#)
Nicotinamide adenine dinucleotide phosphatase (NADPD), staining of cortical neurons for in schizophrenia [1196](#)
Nicotine
 effect on rate of electrical self-stimulation of brain [1010](#)
 mechanism of action in brain [1011](#)
 positive reinforcement action [1010](#)
Nicotinic acetylcholine receptor [189](#)
 secondary structure of subunit [117](#)

P.1379

Nicotinic acetylcholine receptor-channel
 functional model [201](#)
 three-dimensional model [200](#)
 transmembrane subunits [200](#)
Night blindness, vitamin A deficiency [512](#)
Night vision, role of rods [509-510](#)
Nigrostriatal pathway, dopaminergic neurons in [892-893](#)
Nigrostriatal system, dopaminergic pathway [1201](#) [1203](#)
Nissl stain, layers of neurons in cerebral cortex [326](#)
Nissl substance
 motor neuron [73](#)
 stained ribosomal RNA [91](#)
Nitric oxide
 action at synapses [262](#)
 as neurotransmitter [295](#)
 as transcellular messenger [239](#)
 receptors, in autonomic nervous system [971](#)
 retrograde messenger in long-term potentiation [1262](#)
 second messenger in synaptic transmission [230](#)
 stimulates cGMP synthesis [239-240](#) [295](#)
NMD A See N-methyl-D-aspartate
NO See Nitric oxide
Nociception [430](#)
 neural mechanisms of, versus pain [472-473](#)
Nociceptive afferent fibers
 neurotransmitters [477](#)
 terminate on neurons in dorsal horn of spinal cord [475-77](#)
Nociceptive information
 transmission inhibited by monoaminergic pathways from raphe magnus nucleus to spinal cord [896](#)
Nociceptive neurons
 primary, chemical mediators [478](#)
 synapses with neurons of substantia gelatinosa of spinal cord [476](#)
Nociceptive pain [473](#)
Nociceptive projection neurons, inhibitory descending pathway [486](#)
Nociceptive-specific neurons, in dorsal horn of spinal cord [475](#)
Nociceptors [472](#)
 activation
 by noxious insults [473-475](#)
 and sensitization by chemical mediators [481](#)
 agents that activate or sensitize [480](#)
 as chemoreceptors [442](#)
 classes [473-475](#)
 mediate pain [442-443](#)
 pain [430](#)
 sensitization by thermal injury [479](#)
 types [432](#) [442-443](#)
 viscera, and pain elsewhere in body [475](#)
Node of Ranvier [22](#) [75](#) [85](#)
 action potential repolarization [160](#)
 boost amplitude of action potential [148](#) [148](#)
 regeneration of action potentials [22](#)
 sensory neurons [77](#)
 structure [21](#)
Nodose ganglion, taste information pathway [642](#)
Nodulus, cerebellum [833](#)
Noebels, Jeff [925](#)
Noggin, neural induction [1024](#)
Non-REM-cells, patterns of activity during REM sleep [940](#)
Non-REM-on cell, mediation of sleep [939](#)
Nonspiny neurons, in cerebral cortex [923](#)
Nondeclarative memory See Memory, implicit
Nonpyramidal cells, in primary visual cortex [533](#)
Nonspindle endings [720](#)
Noradrenergic cell groups, in medulla and pons [890-891](#) [890](#)
Noradrenergic neurons
 effects of antidepressant drugs on [1218-1219](#)
 in locus ceruleus [895](#)
 in pons [891](#)
Noradrenergic pathways
 drugs effect in treatment of depression act on [1216](#)
 originating in locus ceruleus [1215](#) [1216](#)
Noradrenergic receptors, linked to second-messenger systems [1216](#)
Norepinephrine
 abnormal function in narcoleptic dogs [951](#)
 as small-molecule neurotransmitter [282-283](#)
 biosynthesis and structure [282-283](#)
 biosynthetic enzymes [281](#)
 contribution to primary generalized seizures [925](#)
 effect on

feeding responses [1004](#)
heart [967](#)
high levels in patients with post-traumatic stress disorder [1222](#)
neurotransmitter in autonomic nervous system [970](#)
production varies with neuronal activity [284](#)
receptors for in autonomic nervous system [971](#)
uptake blocked by cocaine [295](#)

Nose, olfactory sensory neurons in [626](#)

Notch protein, role in determining neuronal cell fate [1043](#) [1046](#)

Notch signaling
regulates neuronal cell fate in central nervous system [1045](#)
specifies specification of nerve cell identity [1042](#)

Notch, in cortical progenitor cells [1051](#)

Notochord [1020](#)
inductive signals [1027](#)

Novelty-seeking behavior, human, and gene that encodes D4 dopamine receptor [51](#)

NPY See Neuropeptide Y

NSF See N-ethylmaleimide-sensitive fusion protein

NT-4, blocks formation of ocular dominance columns [1124](#) [1125](#)

NT3, effect on formation of ocular dominance columns [1125](#)

Nuclear bag fibers, muscle spindles [718](#) [719](#)

Nuclear chain fibers, muscle spindles [718](#) [719](#)

Nuclear envelope, neuron [70](#)

Nuclear localization signal [90](#)
on proteins [93](#)

Nuclear pore
neuron [70](#)
role in protein synthesis [93](#)
site of mRNA and ribosome export to cytosol [89](#)
size limitation of proteins that can pass through [94](#)

Nuclear prepositus hypoglossi, neural integration of velocity signal in saccade [790](#)

Nuclei [337](#)
brain, regularity of position and components [332](#) [333](#)
diffusely projecting [343](#)
location of in thalamus [343](#)
organizational complexity [334](#)
relay [343](#)
in right hemisphere, macaque monkey [333](#)
in subcortical regions of brain [331-333](#)
in thalamus [341](#)
relay nociceptive information to cerebral cortex [480-481](#)

Nucleoli, site of ribosomal RNA transcription [89](#)

Nucleus
importation of proteins synthesized in cytosol [93-94](#)
role in protein synthesis [91](#)

Nucleus accumbens
projections of mesolimbic system to [1201](#)
target for action of addictive drugs [1011](#)

Nucleus ambiguus [881](#)
in autonomic response control pathway [975](#)
location and function [884](#) [885](#)
noradrenergic neurons associated with, projections and functions [890-891](#)
pathway of sensory information [974](#)
preganglionic parasympathetic, in brain stem, projections [963](#)

P.1380

Nucleus basalis, abnormalities in Alzheimer disease [1153](#)

Nucleus basalis of Meynert, cholinergic neurons in [896](#)

Nucleus of Clarke's column [448](#)

Nucleus of dorsal raphe, motor circuit for horizontal saccades [791](#)

Nucleus of lateral lemniscus, auditory pathway [604](#)

Nucleus of preoptic area, sexually dimorphic [1137](#)

Nucleus of sixth nerve, control of sleep [941](#)

Nucleus of solitary tract, taste information pathway [642](#)

Nucleus of the solitary tract
in autonomic response control pathway [975](#)
C2 adrenergic neurons in [8892](#)
and homeostasis [965-966](#)
location and function [882-883](#)
modulation of autonomic function [972-973](#)
noradrenergic neurons in [890](#)
pathway of visceral sensory information [974](#)

Nucleus prepositus hypoglossi, motor circuit for horizontal saccades [791](#)

Nucleus proprius [448](#)

Nucleus raphe magnus, inhibitory descending pathway, pain [486](#)

Nucleus reticularis, GABA-ergic inhibitory neurons and rhythmic firing of thalamic relay neurons during non-REM sleep [940](#)

Nucleus reticularis pontis oralis
PGO-on cells in [942](#)
REM-on cells, activity during REM sleep [943](#)
REM-waking-on cells, fire during REM sleep and non-REM sleep [942-943](#)

Nucleus reticularis pontis oralis/caudalis, control of sleep [941](#) [941](#)

Numa, Shosaku [198](#)

numb, in cortical progenitor cells [1051](#)

Numb protein
inhibits notch signaling and controls nerve cell fate [1043](#)
role in determining neuronal cell fate [1045](#)
subcellular localization in neuroblasts during mitosis [1043](#)

Nusslein-Volhard, Christiane [1032](#)

Nystagmus [809](#) [812](#) [814](#)
cerebellar infarction [1313](#)
defective optokinetic [813](#)

Penfield, Wilder [12](#) [344](#) [387](#) [925](#) [911](#) [1229](#)

Penicillin, produces generalized epilepsy in cats [923](#)

Peptide A, precursor structure [291](#)

Peptide hormones, released by hypothalamic parvocellular neurons [979](#)

PER protein
circadian rhythm [44](#)
dimerization with TIM protein [46](#)

Percept, pain as [472–491](#)

Perception [407–649](#) [473](#)
beginning in receptor cells [407](#)
as constructive process [383](#)
contributions of M and P cells [532](#)
different modalities processed similarly by different sensory systems [381–382](#)
functional organization [337–348](#)
holistic nature [493](#)
internal cellular representation required for [381–303](#)
internal construction of world [412](#)
motion, depth, and form [548–571](#)
multimodal association areas of cerebral cortex as anatomical substrate for [350](#)
nature of [408](#)
neural representation [383](#)
pain [472–491](#)
pathway of processing [319](#)
space See Vestibular system
spatial, impairment after middle cerebral artery infarction [1307–1308](#)
visual [492–506](#) See also Visual perception
weakness in empiricist argument [412](#)

Perceptual correlates, posture [829–830](#)

Perceptual functions, role of cerebral hemispheres [322](#)

Perforant fiber pathway, hippocampus [1257](#)

Perforant pathway
hippocampus [1259](#)
long-term potentiation is associative [1260](#)

Performance, affected by arousal level [983](#)

Periaqueductal gray matter [482](#)
in autonomic response control pathway [975](#)
behaviorally coordinated patterns of autonomic response [973](#)
inhibitory descending pathway, pain [486](#)
pathway of sensory information [974](#)

Periglomerular interneurons
inhibitory synapses with mitral cell dendrites in glomerulus [632](#)
of factory bulb [630](#) [631](#)

Perilymph [803](#)

Perilymphatic duct [802](#)

period gene
circadian rhythm in flies [45](#)
flies, role in circadian rhythm [44](#)
fly, molecular polymorphisms in and circadian rhythm [42](#)

Periodic limb movement disorder, sleep pathology [955](#)

Peripersonal space [384](#) [402](#)

Peripheral motor axons, conduction velocities in neuropathies [699](#)

Peripheral myelin protein [22](#)
duplication of gene causes Charcot-Marie-Tooth disease [83-84](#)
mutations of gene for in hereditary peripheral neuropathies [709](#)

Peripheral nerves
afferent fiber groups in [444](#)
conduction velocities [444](#)
cutaneous innervation map [734](#)
diseases, acute or chronic [701-704](#)
provide permissive environment for regeneration of central axons [1112](#)

Peripheral nervous system [335](#)
anatomical but not functional distinction from central nervous system [334-335](#)
dependence on neurotrophic factors [1059](#)
factors contributing to regenerative capacities [1110](#)
greater capacity for nerve regeneration [1109-1110](#)
myelination in [81](#)
somatic and autonomic divisions [335](#)

Peripheral neuropathies [696](#)

Peripheral neuropathy
inherited, Charcot-Marie-Tooth disease [83-84](#)
symptoms [702](#)

Peripheral receptors, in motor system [667](#)

Peripheral sensors, fragment tactile information about object [452](#)

Perirhinal cortex [1232](#)

Peristalsis, control by enteric nervous system [968](#)

Perisylvian language areas, damage to connections with transcortical sensory area [1181](#)

Perivascular space, cerebrospinal fluid [1294](#)

Periventricular fiber system, hypothalamus [978](#)

Periventricular nucleus [976](#)

Permeability [135](#)
changes in during signaling [138-139](#)
membrane to ion, calculation [132-134](#)
membrane [135](#)
use in Goldman equation [132](#)

Peroxisomes
importation of proteins synthesized in
cytosol [93-94](#)
neuron [70](#)
role in protein synthesis [91](#)

Persephin, neurotrophin receptor [1057](#)

Persistent vegetative state, as result of bilateral forebrain damage [900](#) [901](#)

Personal neglect syndrome [393](#) [393-394](#)

Personal space [384](#)
internal representation explored by study of touch and proprioception [385](#)
modifiable by experience [388-391](#)
orderly representation in brain studied at cellular levels [384-388](#)

Personality
anatomical localization of affective traits and aspects [14-15](#)
disorders [1192](#)
twin studies [42](#)

PET See Positron emission tomography

Petersen, Steve [846](#)

Petit mal seizure See Seizure, absence

Petrosal ganglion
innervation of taste buds [643](#)
taste information pathway [642](#)

Phantom limb syndrome, imaging studies of [390](#)

Pharynx, taste information pathway [642](#)

Phase lag, in feedback systems [656-657](#)

Phase locking, cochlear nerve [603](#)

Phe-Met-Arg-Phe-amide
activates S-type K⁺ channels [243](#)
precursor structure [291](#)
neuroactive peptide [289](#)

slow synaptic action mediated by opens same S-type K⁺ channel closed by serotonin [246](#)

Phencyclidine

inhibits NMDA receptor-channel [213](#)

molecular targets and effects [1206](#)

Phenelzine, antidepressant, structure [1213](#)

Phenobarbital, as anticonvulsant [911](#)

Phenothiazines, treatment, schizophrenia [1197](#) [1197](#)

Phenotype [38](#)

relationship with genotype [38-40](#)

Phenylethylamines, as false transmitters [286](#)

Phenylketonuria, example of interaction of genes and environment [36-37](#) [37](#)

Phenytoin, treatment, prolonged repetitive seizures [919](#)

Pheromone receptors [634](#)

pattern of expression in vomeronasal organ [635](#) [635](#)

P.1385

Pheromones, chemical messengers [633-634](#)

Phineas Gage, reconstruction of injury to temporal lobes [353](#)

Phoenix, Charles [1136](#)

Phonemic paraphasias, in Wernicke aphasia [1179-1180](#)

Phonological store, left supramarginal gyrus [360](#)

Phonology, grammar [1171](#)

Phosphatase-1 [249](#)

Phosphatidylinositol4, 5-bisphosphate, hydrolyzed phospholipid [236](#)

Phosphene [418](#)

Phosphoinositol system [231](#)

Phospholipids, hydrolysis of in cell membrane [236](#) [237](#)

Phosphoprotein phosphatases, regulate levels of phosphorylation [249](#)

Phosphorylation

cascade, in hippocampus [249](#)

hydroxyl group in Ser, Thr, or Tyr residues by protein kinases, post-translational protein modification [93](#)

ion channels, effect on functional state [251](#)

levels regulated by phosphoprotein phosphatases [249](#)

neuronal, dopamine role in [249](#)

of proteins in Golgi complex [96](#)

receptor [230](#)

sequence, and specificity of protein kinases [235](#)

Photopigments, cones [573](#) [575](#) [576](#)

as transmembrane proteins [576](#)

Photoreceptors

absorption of light by visual pigments in [510](#)

activation of pigment molecules reduced cytoplasmic concentration of cGMP [512-514](#)

dark current [513](#) [531](#)

hyperpolarization [513](#) [514-515](#)

interneurons relay signals from to ganglion cells [520-521](#)

retina [508-510](#) [508](#)

rod and cone [417](#)

slow adaptation to changes in light intensity [515-517](#)

transduction of

light into electrical signals [521](#)

stimulus energy into neural activity requires intracellular second messengers [417](#)

types of in color vision [573-575](#)

Phototransduction

closing of cation channels during in photoreceptors [512](#)

mechanism [510-515](#)

role of

calcium [514](#)

cGMP [521](#)

G protein [521](#)

Phrenology [7](#)

map of skull [7](#)

Physical stimulus, transformation into electrical activity [30](#)

Physiological monitoring methods, sleep [949](#)

Physostigmine, reverses symptoms of myasthenia gravis [299](#)

Pillar cells, organ of Corti [596](#)

P1P2 See Phosphatidylinositol 4, 5-bisphosphate

Piriform cortex, olfactory information processing [633](#)

Pitch, sense of, tonotopic maps underlying [1127](#)

Pituitary, anterior, control of hormone release by peptides of parvocellular neurons [979](#)

Pituitary gland [367](#)

anterior

hormone-dependent sex difference [1134](#)

hormones and hypothalamic substances regulating [980](#)

hormonal secretions regulated by hypothalamus [322](#)

and hypothalamic control of endocrine system [978-979](#)

pathways of control by hypothalamus [977](#)

posterior

absence of blood-brain barrier [1293](#)

hormones [979](#)

PKA, ACh receptor as substrate for [248](#)

PKA See Protein kinase A

PKC, ACh receptor as substrate for [248](#)

Place cells

firing patterns [1267](#)

hippocampus [1264-1267](#)

long-term potentiation fine-tunes properties of [1267](#)

Place code [603](#)

Place cues [992](#)

Place field, hippocampus [1264](#)

Place-preference [992](#)

Planning

behavior, tests of [358](#)
behavioral, disturbed by lesions of prefrontal association area [361–362](#)
motor, affected by lesions in prefrontal association area [356–357](#)
prefrontal association area [356](#)
role of frontal lobe [9](#)
and voluntary movement [756](#)

Plasma cell diseases, chronic neuropathy in [702](#)

Plasmalemma membrane
in bulk endocytosis [98](#)
maintenance in steady state by endocytosis [97](#)
manufacture on rough endoplasmic reticulum [103](#)
membrane anchor on proteins destined for [96](#)
neuron [69](#)
synthesized and modified in endoplasmic reticulum [94–96](#)
vesicles that fuse with [97](#)

Plasmapheresis, treatment of symptoms of autoimmune myasthenia gravis [306](#)

Plasticity
chemical synapses [34](#)
hypothesis, in nervous system [34](#)

Plateau potentials [743 744](#)

Platelet-derived growth factor, and diversification of glial cells in rat optic nerve [1048](#)

Plato [897 1317](#)

Posterior parietal association cortex [402](#)
 receives input from hippocampus [392-395](#)
 representation of imagined and remembered extrapersonal space in [392-395](#)
Posterior parietal cortex [453](#) [501](#) [757](#)
 areas 5 and 7, integrative somatosensory responses for movement [465](#)
 area 7, integration of tactile and visual stimuli [465](#)
 effect of lesions in on visual system [498](#)
 function [351](#)
 lesions produce complex sensorimotor abnormalities [469](#)
 motion, depth, spatial information [502](#)
 and neural mechanisms of selective attention [400](#) [401](#)
 roles [453](#)
 somatosensory cortical area [452](#)
 and visual attention [565](#)
Posterior parietal cortical areas, mental rehearsal of movement [771](#)
Posterior parietal lobe, damage to produces agnosia [392-393](#)
Posterior parietal pathway
 cross talk with inferior temporal pathway [567-568](#)
 visual [500-501](#)
Posterior pial arteriolar plexus [1314](#)
Posterior radicular artery [1314](#)
Posterolateral fissure, cerebellum [833](#)
Postganglionic fibers, peripheral autonomic effector organs [962](#)
Postganglionic neurons
 pathways [963](#) See also Autonomic motor neurons
Postganglionic sympathetic neurons
 ATP as cotransmitter with norepinephrine [970](#)
 release of norepinephrine [970](#)
Postherpetic neuralgia [473](#)
Postictal period [913](#)
Postspike facilitation [767](#)
Postsynaptic cell [23](#)
 axo-axonic synapses inhibit or facilitate transmitter release [276](#)
Postsynaptic density protein, PSD-95 [221](#)
Postsynaptic inhibition [275](#)
Postsynaptic membrane [188](#)
Postsynaptic neuron, impact of inhibitory current [225](#)
Postsynaptic potential, high rate of stimulation of presynaptic neuron produces gradual increase in amplitude [275](#)
Posttetanic potentiation [274](#)
Postural changes, conscious ideas about have physiological consequences [830](#)
Postural disturbances, learning of appropriate anticipatory responses [820](#) [820](#)
Postural equilibrium [817](#)
Postural reflexes [816](#) [817](#)
Postural set [819](#)
Postural system, functions [816](#)
Posture [816-831](#)
 adjustment, contribution of vestibular system [824](#)
 contributions of neck [821-824](#)
 control
 adaptation to specific behaviors [819-820](#)
 adaptive
 learned during locomotion [821](#)
 requires intact cerebellum [820-821](#)

feed-forward and feedback components [819](#)
goals [830](#)
by medial brain stem pathway [668](#)
by medial descending systems [663](#)
destabilizing effect of optokinetic stimulation [828](#)

P.1387

disturbance, anticipatory motor action in response to [819](#)
and equilibrium [817](#)
feed-forward control in motor systems for control of [657](#)
and locomotion, adaptability [822](#)
maintained by cerebellum [322](#)
modulation by medial and lateral reticulospinal pathways [896](#)
and movement [817-821](#)
perceptual correlates [829-830](#)
readjustment preceded by anticipatory motor action [817-818](#) [818](#)
stability, collaboration of vestibulospinal and cervicospinal reflexes to maintain [823-824](#) [823](#)
vertical, maintained by vestibulospinal reflexes [810](#)
vestibular contributions [821-824](#)

Potassium

activation of nociceptors [480](#)
astrocytes main correct ion concentration [20-21](#)
chemical intermediary for pain [442](#)
extracellular, effect on excitability of neurons in seizure focus [919](#)
permeability of synaptic channels at end-plate to [192](#)
time course of concentration in cerebral cortex [1291](#)

Potassium channel

depolarization-activated and Ca²⁺-activated, molecular structure [168](#)
inactivating, molecular structure [168](#)
noninactivating, molecular structure [168](#)
electrical properties of [133](#)
inward-rectifier, molecular structure [168](#)
several, as single equivalent electric structure comprising a battery in series with a conductor [134](#)

Potassium current

calculation of voltage-gated K⁺ conductance from [154-155](#)
hyperpolarization of thalamic relay nuclei [898](#)
passive, balanced by active K⁺ fluxes driven by Na⁺-K⁺ pump [135](#)

Potassium equilibrium potential [128](#)

Potassium ion channel

passive, as equivalent electrical circuit [134](#)
substances that block [154](#)

Potassium ions

channels permeable to opened by ACh binding in postsynaptic muscle cell [199](#)
conducted along with Na⁺ in glutamate-gated channels [212](#)
contribution of efflux of to transmitter release [254-255](#)
diffusion out of cell [128](#)
diffusion out of glial cells [128](#)
distribution across cell membrane [128](#)
distribution across neuronal cell membrane at rest [128](#)
and electric potential of nerve cell membrane [27](#)
flux across cell membrane [129](#)
free energy of binding [109](#)
increased permeability for in falling phase of action potential [151](#)
model for selectivity of ion channels for [106-107](#)
nerve cells permeable to at rest [129](#)
passive flux balanced by active pumping of ions [131](#)
resting ion channels in glial cells selective for [128-129](#)
nerve cells selective for, in addition to Na⁺ and Cl⁻ ions [129-131](#)
simultaneous flow with Na⁺ produces end-plate potential [193](#)

Potassium-selective ion channel, structure solved by X-ray crystallography [120-123](#) [122](#)

Potential difference

circuit analysis [1284-1285](#)
electrical parameter [1280](#)
factors affecting [1282](#)

Potentiation [274](#)

Potter, Lincoln [300](#)

Power grip

activity of single neuron during [772](#)
control by descending pathways [769](#) [770](#)

Practice, movement, shift of neural control from supplementary motor area to primary motor cortex [774](#)

Preattentive process, visual perception [502-503](#)

Preattentive scanning [503](#)

Precentral gyrus [9](#)

Preocerebellar nuclei [842](#)

Precision grip

activity of single neuron during [772](#)
population of primary motor cortex cells active during [769](#)

Precursor RNA, transcribed and spliced in nucleus [89](#)

Prefrontal association area

dopaminergic innervation [361](#)
effect of lesions of [356-357](#)
functions [356](#)
illustrate function of association cortex [356-362](#)
lesions of disturb behavioral planning [361-362](#)

Prefrontal association cortex

common output targets of [363](#)
inputs to premotor cortex [355](#)
prominence of particular cell layers [328](#)

Prefrontal circuit, basal ganglia, links thalamus and cerebral cortex [858](#)

Prefrontal cortex [757](#)

attentional signals that modulate neurons in visual system originate in [401](#)
delayed response task testing [359](#)

disorders of action associated with [866](#)
dorsolateral, increased blood flow in cocaine craving [1008](#)
and episodic knowledge [1237-1239](#)
evaluative component of emotion [985](#)
left, in encoding of episodic memory [1238](#)
projections of mesocortical system to [1202](#)
right, in retrieval of episodic memory [1238](#)
subgenual region
abnormality of function in depressions [1212-1213](#) [1212](#)
effects of lesions in [1213](#)
and visual attention [505](#)

Prefrontal region, contains map of contralateral visual field that is used for working memory [359](#)

Preganglionic neuron [962](#)

Preganglionic sympathetic neurons, column in intermediolateral horn of spinal cord [963](#)

Prehension [846](#)

Premamillary preparations, study of stepping [738-739](#)

Premotor areas [775](#)

Premotor areas [775](#)
contributions to motor planning [770-777](#)
direct electrical stimulation stimulates movement [760](#)
mental rehearsal of movement [771](#)
motor maps of face and extremities in [760](#)
movement-related neurons in [779](#)
number of [760](#)
projections [663](#)
to primary motor cortex, and spinal cord [760](#)
role in coordinating and planning complex movement [663](#)

Premotor cortex [347](#) [347](#) [756](#) [757](#) [758](#) [761](#)
function [355](#)
inputs to [355-356](#) [761](#)
location [671](#)

Premotor neurons [696](#)
degeneration in amyotrophic lateral sclerosis [700](#)

Premotor-cerebello-rubro-cerebellar loop, role in mental rehearsal of movements and motor learning [846](#)

Preoptic area
baroreceptors in [1006-1007](#)
hypothalamus [977](#)

Preparations, spinal, types used in study of stepping [738-739](#) [740](#)

P.1388

Preparatory potential, negative potential in supplementary motor area [771](#)

Preparatory set activity, primary motor cortex neurons [764-765](#)

Preprohormone [288](#)

Presenilin 1 and 2 genes, genetic risk factors in Alzheimer disease [1156](#)

Presupplementary motor area
learning motor programs [773](#)
role in learning sequences of movements [771-774](#)

Presynaptic bouton, structure [189](#)

Presynaptic cell [22](#)

Presynaptic contacts, on primary dendrites of motor neuron [76](#)

Presynaptic differentiation, factors that organize [1100](#)

Presynaptic facilitation [275](#)
mechanisms of [275-276](#)

Presynaptic inhibition [275](#)
mechanisms of [275](#)

Presynaptic membrane [188](#)

Presynaptic neuron, high rate of stimulation produces gradual increase in postsynaptic potential [275](#)

Presynaptic terminal [22](#) [23](#) [182](#)
active zones [261](#)
all-or-none transmitter release from active zones [261](#)
axo-axonic synapses on regulate intracellular free calcium [275-276](#)
blocking voltage-sensitive Na⁺ and K⁺ channels in [255](#)
boutons [188](#)
Ca²⁺ influx triggers neurotransmitter release [256](#)
depolarization of regulates neurotransmitter release [253-255](#)
exocytosis events [265](#)
neuronal [21](#)
sensory neurons, structural changes in long-term habituation and sensitization [1256](#)

Pretectum
controls pupillary reflexes [527-528](#)
optic nerve projections to [517](#)
retinal projections to [523](#) [527](#)

Prevertebral ganglia [963](#)

Primary afferent fiber [431](#)

Primary auditory cortex [604](#)
columns in [609](#)
left, affected in conduction aphasia [1180](#)
parallel processing and conformal mapping in [609](#)
tonotopic maps in [609](#)

Primary cortex, two different meanings for term [350](#)

Primary fissure, cerebellum [833](#)

Primary motor cortex [326](#) [346](#) [355](#) [756](#) [757](#) [758](#) [761](#) [775](#)
adaptation of movements to new conditions [764-770](#)
blood flow in during finger movements [773](#)
comparisons of somatotopic organization in monkey and human [757](#)
corticomotoneuronal cells in [765](#)
distribution of sites controlling individual muscle [759](#)
execution of movements [764-770](#)
fibers originating in and terminating in ventral horn of spinal cord [346](#)
functional organization changed after transection of facial nerve in rat [762](#)
hand-control area [768](#) [771](#)

highest level of motor control [663](#)
increased representation of movement with practice [763](#)
individual movement of fingers [767-770](#)
inputs from primary somatosensory cortex and posterior parietal areas 5 and 7 [760-761](#)
levels of functional organization [770](#)
lobes and location [351](#)
location [671](#)
magnetic stimulation [759](#)
motor map in [323](#)
neurons can be activated by peripheral stimulation [767](#)
organization of voluntary movement [758-759](#)
populations of neurons in encode movement direction [765-766](#)
premotor cortical areas project to [760](#)
projections of thalamic neurons to [843](#)
prominence of particular cell layers [328](#)
relationship to association regions [352](#)
representations of individual muscles overlap [759](#)
somatotopic organization [347](#)

Primary sensory cortex
ascending dorsal column-medial lemniscal pathway [342](#)
lobes and location [351](#)
relationship to association regions [352](#)
variation of body surface maps of among individuals [1274](#)

Primary somatic sensory cortex [757](#)
area 2, feature-detecting neurons [466](#)
effects of lesions [468](#)
integrates information about touch [452-458](#)
location and projections [452](#)
processing of sensory information in cerebral cortex [345](#)
properties of neuronal receptive fields due to convergent and divergent connections in relay nuclei [456](#)
receptive fields of
cells comprising column in [456](#)
neurons in [455](#)

Primary somatosensory cortex [326](#)
contains body map for each submodality of sensation [387-388](#)
each area has complete representation of body surface [389](#)
increased use of fingers enlarges representation of hand in [390](#)
inputs to
premotor cortex [355](#)
primary motor cortex [760-761](#)
mapping of [387](#)
modification of cortical representation of hand [389-390](#)
pattern of connections genetically programmed and also develops through learning [388-389](#)
representation of hand with fused and nonfused digits [391](#)
somatic sensory information conveyed to in parallel pathways [449](#)
vestibular projection to [813](#)

Primary spindle endings [720](#)

Primary visual cortex [326](#) [775](#)
anatomical layers [533](#)
blobs, stripes, and interblobs [501](#)
cells in converge on cells in association cortex [324](#)
columnar units linked by horizontal connections [540-543](#)
combines information from two eyes [560-561](#)
complex cells, feature abstraction by progressive convergence [535-537](#)
each half of visual field represented in contralateral [532](#)
information flow [533](#)
input and output [533](#)
interconnections with V2 [549](#)
intracortical connections [533](#)
lesions, blindsight [1318](#)
links between columns and horizontal connections [542](#)
neurons not in distinct color classes [582-583](#)
organization [549](#)
of blobs in [539](#)
into functional modules [537-543](#)
of orientation columns, ocular dominance columns, and blobs [541](#)
of retinal input into building blocks of visual images [532-537](#)
orientation columns in [538](#)
outlines of visual image decomposed into short line segments [533-535](#)
prominence of particular cell layers [328](#)
response of cells to moving plaid pattern [554](#)
retinal projections to [543](#) See also Ocular dominance columns
separation of function of dorsal and ventral pathways [549-550](#)
structure [532](#)

P.1389

two types of cells [533-535](#)
visual system [496](#)

Priming [1230](#)

Principal neurons [323](#)

Principal sensory trigeminal nucleus [881](#)
function [882](#)

Principal sulcus
cortex surrounding and tasks that require working memory [357-361](#)
memory fields in neurons of [359](#)
neurons in track working memory [361](#)

Principal trigeminal nucleus, pathway of sensory information [446](#)

Pro-opiomelanocortin, precursor structure [291](#)

Proctolin, neuroactive peptide [289](#)

Prodromal signs, schizophrenia [1192](#)

Prodynorphin [487](#)

Proenkephalin [487](#)

Programmed cell death [1041](#) See also Apoptosis

Progressive bulbar palsy [700](#)

Prohormone [288](#)

Projection interneuron, functional regions [28](#)

Projection neurons [323](#) [329](#) [330](#) [335](#)
afferent connections with in spinal cord [667](#)
dorsal horn of spinal cord, nociceptive afferent fibers terminate on [474](#)
inhibition in sensory relay nucleus enhances contrast between stimuli [427](#)

Projections
from cell layers of neocortex [329](#)
retinal [526-529](#)

Prolactin
inhibitory control [979](#)
neuroactive peptide [289](#)
precursor structure [291](#)

Prolactin release-inhibiting hormone, hypothalamic [980](#)

Prolactin-releasing factor, hypothalamic [980](#)

Proneural genes [1045](#)

Proneural region, ectodermal [1043](#)

Proneural strips [1046-1047](#)

Proopiomelanocortin [487](#)
neuroactive peptide [288](#)
precursor polypeptide of opioid peptides [485](#)

Propagation [145](#)
factors affecting velocity of during action potential [147-148](#)

Propranolol
effect on storage of emotional events [992-993](#)
treatment, post-traumatic stress disorder [1222](#)

Proprioception [430](#) [443](#)
dorsal column-medial lemniscal system is pathway for perception [447-448](#)
mediated by
dorsal root ganglion neurons with encapsulated peripheral terminals [431](#)
mechanoreceptors in skeletal muscle and joint capsules [443](#)
study of to explore internal representations of personal space [384](#)
timing and amplitude of stepping patterns [748](#) [749](#)

Proprioceptive reflexes, role in voluntary and automatic movements [726-730](#)

Proprioceptors, automatic regulation of stepping [747](#)

Propriospinal interneurons, short and long [668](#)

Propriospinal neurons
afferent connections with in spinal cord [667](#)
organization of axons in spinal cord [667](#)

Prosencephalon [1021](#) [1022](#) [1022](#)

Prosencephaly [1029](#)

Prosody [14](#) [1171](#)

Prosomeres [1035](#)

Prosopagnosia [499](#) [500](#) [994](#) [1237](#)
lesions causing [499-500](#)

Prostaglandin D2, hypnogenic properties [943](#)

Prostaglandins
action at synapses [262](#)
effect on nociceptors [481](#)
mediation of [237](#)
and nociceptor sensitization [477-478](#) [480](#)

Prostigmine, enhance and prolong miniature end-plate potentials [257](#)

Protanopia [584](#)

Protection hypothesis, brain development [1139](#)

Protein coats, generation of transport vesicles [96](#)

Protein folding, role of chaperones [91-92](#)

Protein kinase A (PKA)
activation in
ax on growth cones [1078](#)
long-term potentiation [1260](#)
in long-term facilitation [1257](#)
pathways of action in sensitization [1250-1251](#)
role in
learning and short-term memory in *Drosophila* [1258](#)
sensitization [1250-1251](#)

Protein kinase C
isoforms [238](#)
regulation [235](#)

Protein kinases
activation by second messengers [251](#)
modification of gating by changing phosphorylation state [159](#) See also cAMP-dependent protein kinase
specificity [235](#)

Protein phosphorylation, effect on ion channel gating [114](#)

Protein tyrosine kinases, and neurotrophin mechanism of action [1058](#)

Proteins
cellular organelles responsible for synthesis and processing of [91](#)
cotranslational modifications [92-93](#)
cytosolic
enzymes that catalyze metabolic reactions [90](#)
fibrillar elements of cytoskeleton [90](#)
importation by nucleus, mitochondria, and peroxisomes [93-94](#)
phosphorylation and dephosphorylation [93](#)
ubiquitination [93](#)
export signals [93](#)
function defined by amino acid sequence and secondary and tertiary structure [91-92](#)
kinases, similar regulation of [235](#)
membrane, synthesis and modification in endoplasmic reticulum [94-95](#)
modification during or after synthesis [92-93](#)
nuclear localization signals [93](#)
organelles responsible for synthesis and processing [93](#)

- post-translational modifications [90](#) [92–93](#)
- reversibility of post-translational modifications [93](#)
- secretory
 - method of formation in endoplasmic reticulum [95](#)
 - processing in Golgi complex and export [96–97](#)

Sensory cortices, blood flow in during finger movements [773](#)

Sensory decussation [342](#) [446](#)

Sensory experience
and fine-tuning of synaptic connections [1115-1130](#)
refinement or modification of connections in auditory system [1127](#)

Sensory experiences, natural stimuli versus stimuli used on neurological examination [441](#)

Sensory fibers
extensor, excitatory pathways of information from to extensor motor neurons [748](#)
muscle
classification [720](#)
selective activation [720](#)
propagation of action potentials in and perception of pain [473](#)

Sensory function
integration with motor function [349-380](#)
role of midbrain [8](#)
temporal and spatial contrast [425](#)

Sensory information
ascending pathways from limbs and trunk to thalamus and cerebral cortex [446-447](#)
coding of [411-429](#)
compared with biological set points by hypothalamus [975](#)

P.1397

features of [428](#)
from unimodal areas of cerebral cortex, converges in multimodal areas [354-355](#)
gating and modulatory role of thalamus [322](#)
hierarchical processing of by somatosensory system [338-341](#)
moving limbs, regulate stepping patterns [747-750](#)
parallel and serial processing in primary somatic cortex [452](#)
parallel processing of [319](#)
processed
sequentially and in parallel [352](#) [354](#)
in stages in central nervous system [428](#)
processing
of emotional information [990](#)
principles [352-362](#)
by spinal cord [8](#)
and regulation of movement [713](#) See also Receptors, sensory; Stimulus
spatial and temporal judgments, activity of dentate nucleus during [848](#)
supplied to hypothalamus [975](#)
transmission to thalamus [448](#)
visceral, distributed by nucleus of the solitary tract [966](#)

Sensory initiation, role of posterior parietal cortex [453](#)

Sensory inputs
transient, difficulty in processing quickly in dyslexia [1185](#)
unimodal, converge on neurons in prefrontal cortex, parietotemporal cortex, and limbic cortex [355](#)

Sensory loss
areas of after middle cerebral artery infarction [1307-1308](#)
diffuse hypoperfusion [1313](#)
after occlusion of carotid artery [1309](#)

Sensory maps, in spinocerebellum [842-843](#)

Sensory modality, determined by stimulus energy [414-418](#)

Sensory neurons
adaptation [424-425](#)
anatomy [76](#)
axonal path in spinal cord [77](#)
conducts information from periphery to central nervous system [76-77](#)
connections with motor neurons in spinal cord [74](#)
develops from neural crest cells [1047](#)
diseases attacking [33](#)
ending in soleus muscle [74](#)
frequency of action potentials encodes stimulus intensity [421-423](#)
firing rates
encode stimulus magnitude [423](#)
and intensity of stimulation over time [424](#)
functional regions [28](#)
hearing, spatially organized according to sensitivity [419](#)
higher-order, receptive fields have both excitatory and inhibitory regions [427](#)
information flow to motor neurons is divergent and convergent [79](#)
and nuclei, in gray matter of dorsal horn of spinal cord [338](#)
populations of convey sensory information [426](#)
receptive fields define spatial resolution of stimulus [418-419](#)
require neurotrophins for survival [1057](#)
S-type K⁺ channels closed by slow synaptic action mediated by serotonin [244](#)

sensitization [1256](#)
smell, spatially organized according to sensitivity [419](#)
spatial distribution conveys information about stimulus [418–419](#)
structural changes in presynaptic terminals in long-term habituation and synapse selectively on motor neurons [1106](#)
in reflex [32](#)
taste, spatially organized according to sensitivity [419](#)
transformation of physical stimulus into electrical activity [30](#)

Sensory pathways
different usage of and variation of cortical body surface maps among individuals [1274](#)
modulated by descending pathways from brain stem to spinal cord [896](#)

Sensory perception
as constructive process [1239](#)
influence of locus ceruleus [896](#)

Sensory physiology [412](#)

Sensory processing
networks, hierarchical organization [416](#)
not distributed symmetrically in cerebral hemispheres [363–365](#)

Sensory psychophysics [412](#)

Sensory receptors [414](#)
density in retina and size of receptive field determine resolution of visual image [420](#)
density of innervation and neural map [323](#)
tuning curves [418](#)

Sensory representations, direction of behavior [653](#)

Sensory signals, role in reflex [32](#)

Sensory signs, spinal cord lesions [732–734](#) [734](#)

Sensory stimulus
change in membrane potential produced by transformed into digital pulse code [421](#)
fidelity of in somatic sensory cortex [461](#) [463](#)

Sensory system, somatic
dorsal root ganglion neuron as sensory receptor for [431–432](#)
somatic, modalities [430](#)

Sensory systems [416](#)
attributes of stimulus mediated by [412–414](#) [413](#)
common plan [425–128](#)
peripheral receptive surface and topographical representation [323](#)
process information in serial pathways [426–427](#)

Sensory threshold [421](#)
modified by psychological and pharmacological factors [422](#)

Sentence, deep structure versus surface structure [1171](#)

Septum pellucidum [367](#)

Septum, developing forebrain [1036](#)

Serial pathways
sensory systems process information in [426–427](#)
in visual system [505](#)

Serial processing
attentive visual system [503](#)
basal ganglia-thalamocortical circuits [859](#) See also Parallel processing
stimulation of brain's higher-level cognitive processes [34](#)

Serine proteases, biosynthesis of neuroactive peptides [288](#)

Serine-threonine kinases, activation by bone morphogenetic protein [1029](#)

Somatic nervous system
 compared with autonomic nervous system [960](#)
 organization of motor pathways [961](#)

Somatic sensation See Sensation, somatic

Somatic sensory cortex [342](#)
 accurate representation of spatial detail [461](#) [463](#)
 contains multiple body maps [469](#)
 cortical map of body surface represents density of innervation [469](#)
 detailed representations of embossed letters in area 3b [464](#) [465](#)
 disruption of synaptic transmission effect on finger coordination [469](#)
 distinct areas process stimulus features in parallel [465-468](#)
 each of four regions contains complete body map [460](#)
 functional modules of cortical processing [457](#)
 inhibitory responses generated by interneurons in dorsal column nuclei, thalamic ventral posterior lateral nucleus, cortex [461](#)
 input
 organized in columns by receptive field and modality [456-458](#)
 of receptors to each region of [459](#)
 lesions produce sensory deficits [468-469](#)
 major divisions [453](#)
 neurons have complex feature-detecting properties [463-468](#)
 parallel processing of information for stereognosis [467](#)
 postcentral gyrus, pathway of sensory
 information [446](#) See also Cortical neurons; Primary somatic sensory cortex; Secondary somatic sensory cortex
 spatial resolution correlated with innervation density of skin [459-461](#)
 synchronized firing in different areas to bind stimulus features [468](#)
 topographic representation of body in each of four Brodmann's areas [458](#)

Somatic sensory system [319](#)
 information conveyed in parallel pathways to primary somatosensory cortex [449](#)
 modalities [449](#) See Sensory system, somatic

Somatic [430](#)

Somatosensory cortex [345](#) [347](#) [453](#)
 Brodmann's area 3b, termination of axons of ventral posterior lateral nucleus of thalamus [344](#)
 contains several somatotopic maps of body surface [345](#)
 language [1174](#)
 neural representations of specific body areas in, maps from evoked potentials [385](#)
 relationship of S-I to S-II cortex [453](#)
 representation of whiskers in [462](#)
 role in processing pain [481-482](#)
 somatotopic representation of portions of body is according to degree of innervation [344-345](#)
 thalamic input and barrel organization in rodents [1037](#) [1037](#)

Somatosensory information
 brought to spinocerebellum by direct and indirect mossy fiber pathways [841-842](#)
 carried by parallel and hierarchical pathways to spinal cord and brain [341](#)
 medial lemniscus as major afferent pathway for [342](#)
 species differences [388](#)

Somatosensory processing, feature-detecting cortical neurons [469](#)

Somatosensory system
 hierarchical organization [416](#)
 hierarchical processing of sensory information [338-341](#)
 receptive field of sensory neurons defines spatial resolution of stimulus [418-419](#)

Somatostatin
 neuroactive peptide [289](#)
 neurons releasing [979](#) [980](#)

Somatotopic map [672](#)
 altered by experience [461](#)
 body surface, in spinal trigeminal nucleus [881](#)
 complete in each of four regions of somatic sensory cortex [460](#)
 in motor cortex [671](#)
 oral cavity and face, in spinal trigeminal nucleus [882](#)
 produced by learning, and biological expression of individuality [1274-1275](#)
 spinocerebellum [841](#) [842-843](#)

Somatotopic organization
 basal ganglia-thalamocortical motor circuit [859](#)
 putamen, movement-related neurons [858](#)

Somatotopy, fractured [842](#)
 in spinocerebellum [841](#)
 Somatotropy [340](#)
 Sonic hedgehog induction of distinct classes of ventral neurons [1029](#)
 morphogen [1027-1029](#)
 patterning of
 neural tube [1025](#) [1026](#)
 ventral neural tube [1027-1029](#)

Sonic hedgehog gene, effects of mutations in [1029](#)

Sound
 deconstruction by cochlea [594](#)
 each hair cell sensitive to specific frequency [598-599](#)

P.1401
 energy amplified in cochlea [599-600](#)
 frequency, basilar membrane as mechanical analyzer [593-597](#)
 frequency code [603](#)
 localization of mediated by relay nuclei in brain stem [606-608](#)
 nature of [591](#)
 place code [603](#)
 processing of in bats [609-610](#) [609](#)
 representation
 of intensity [593](#)
 of stimulus frequency of in cochlear nucleus [605](#) See also Echolocation; Pitch

Sour, taste quality [641](#)

Sour tastant
 mechanism of transduction [639](#)
 signal transduction and blockade of K⁺ channels [641](#)

Source amnesia [1237](#)
Spasticity [666](#)
 pathophysiology [730](#)
 produced by interruption of descending pathways to spinal cord [730](#)
Spatial awareness, perceptual abilities involved [418](#)
Spatial differences
 coarse in skin, Pacinian corpuscles and Ruffini endings roles [436](#)
 fine in skin, Meissner's corpuscle and Merkel disc roles [436](#)
Spatial event plots, area 3b of somatic sensory cortex [465](#)
Spatial frequency, P and M cells [530](#)
Spatial neglect [393-394](#) [393](#) [394](#) [395](#)
Spatial representation, role of hippocampus [1233](#)
Spatial resolution
 accuracy of in somatic sensory cortex [461](#) [463](#)
 increased by pattern of excitation and inhibition in receptive field of dorsal column nuclei neuron [463](#)
Spatial summation [145](#) [223](#) [224](#)
Specific anosmia [634](#)
Specific language impairment syndrome [1172](#)
SPECT See Single photon emission computed tomography
Spectral composition [573](#)
Specular reflections [573](#)
Speech
 and left hemisphere of cerebral cortex [10](#)
 initiation and maintenance, role of frontal cortices of left hemisphere [1182](#)
 insula important for planning and coordinating articulatory movements for [1182](#)
 involvement of each cerebral hemisphere in aspects of [364](#)
 left-hemisphere for right-handed people and most left-handed people [364](#)
 motor and sensory programs of [11](#)
 production, brain areas involved in [1174](#)
Spemann, Hans [1023](#)
Spencer, Alden [1248](#)

 detection of single cortical neuron on motor units [767](#)
 identification of primary motor cortex neurons projecting directly to motor neurons [765](#)
Spikes, single electrical transients, field potentials [913](#)
Spinal accessory cranial nerve (XI)
 in developing hindbrain [1031](#)
 function and dysfunction [874-875](#)
 function [880](#)
Spinal and bulbar muscular atrophy, type of trinucleotide repeats involved in [56](#)
Spinal animals [654](#)
Spinal cat, immobilized, reciprocal pattern of motor activity [746](#)
Spinal cord [9](#) [320](#) [324](#) [347](#) [367](#)
 administration of morphine [487-489](#)
 blood supply [1314](#)
 central pattern generator [743](#)
 circuits for repetitive rhythmic motor patterns [656](#)
 complete transection, sensory and motor effects [732-733](#)
 connections between sensory and motor neurons in [74](#)
 cross sections at different regions [339](#)
 damage to, sensory deficits [733](#)
 descending pathways from brain stem modulate sensory and motor pathways [896](#)
 development [1021](#)
 of cell types [1027](#)
 differences in organization from brain stem [885](#)
 diseases and injuries [468](#)
 distinct terminal patterns in by
 afferents carrying somatic sensory information [447-449](#)
 dorsal and ventral roots [340](#)
 dorsal horn
 laminae [475-477](#)
 local-circuit interneurons integrate descending and nociceptor afferent pathways [488](#)
 nociceptive afferent fibers terminate on neurons in [475-477](#)
 opioid receptors in [487-489](#)
 projection neurons, nociceptive afferent fibers terminate on [474](#)
 substantia gelatinosa, synapses of primary nociceptive neurons with [476](#)
 embryonic development [1025](#) [1026](#)
 function [7](#) [8](#) [320](#)
 gray matter
 afferent connections with local interneurons, propriospinal neurons, projection neurons, and motor neurons [667](#)
 functional regions [447](#)
 hyperexcitability of dorsal horn neurons and hyperalgesia [479](#)
 infarction [1313](#)
 interruption of descending pathways produces spasticity [730](#)
 ipsilateral dorsal horn, neurons mediating sensations of pain and temperature terminate in [448](#)
 major anatomical features [338](#)
 major division of central nervous system [319-320](#)
 major regions of [338-340](#) [339](#)
 medial-lateral arrangement of motor nuclei [668](#)
 methylprednisolone treatment of trauma [1111](#)
 motor circuits [663](#)
 motor neurons modulated by cerebral cortex [669-671](#)
 motor pattern for stepping produced at [740-748](#) [742](#)
 motor patterns generated in absence of sensory signals input [746](#)
 motor pool [1069](#) [1070](#)
 neural networks of and purposeful integration of reflex responses [717-724](#)
 neuronal networks generate rhythmic alternating flexor and extensor muscles [742-743](#)
 partial transection, sensory and motor effects [732-733](#)
 premotor cortical areas project to [760](#)

projections to gray matter [668](#) See also Medial brain stem pathway; Lateral brain stem pathway
rhythm-generating system and complex motor patterns [743](#) [746-747](#)
sacral, contains preganglionic cells of parasympathetic nervous system [963](#) See also Neural tube; Spinal reflexes
sensory and motor signs of lesions [732-734](#) [734](#)
similarity of structure to brain stem [873](#)
somatosensory information from trunk and limbs carried to [338-340](#)
sympathetic pathways outputs to ganglia alongside [963](#)

P.1402

transection [739](#)
hind leg stepping after [740](#) [742](#)
spinal shock followed by hyperreflexia [730-735](#)
and walking [753](#)
variation in size of dorsal and ventral horns [340](#)
variety of reflex circuits [663](#)

Spinal interneurons, in motor system [667](#)

Spinal matter See also Gray matter; White matter

Spinal motor circuits, action modulated by brain stem [668-669](#)

Spinal motor neurons [337](#)
dendritic structure in [76](#)
direct and indirect connections of corticospinal axons [763-764](#)
execute movement [667-668](#)

Substance P

- chemical intermediary for pain [442](#)
- effect on nociceptors [481](#)
- and inflammation symptoms [478–179](#)
- localization in terminal of C fiber afferent in dorsal horn of spinal cord [476](#)
- and nociceptor sensitization [477–478](#)
- precursor structure [291](#)
- release from C fibers [477](#)
- sensitization of nociceptors [480](#)
- striatum [856](#)

Substance P and K, precursor structure [291](#)

Substantia gelatinosa, dorsal horn of spinal cord [475](#) [476](#)

Substantia nigra [332](#)
basal ganglia, inputs and outputs [855](#) [855](#)
dopaminergic neurons in [896](#)
dopaminergic synapses [857](#)
inhibitory input from caudate nucleus in saccades [793](#)
midbrain, location of dopaminergic tracts [283](#)
nucleus in midbrain [322](#)

Substantia nigra pars compacta
degeneration of dopaminergic neurons in Parkinson disease [862](#)
dopaminergic neurons in [892](#)

Substantia nigra pars reticular, convergence of basal ganglia circuits [858](#)

Subthalamic nucleus
basal ganglia [855](#) [855](#)
glutamatergic cells of [855](#)
dopaminergic synapses [857](#)
excessive activity and production of parkinsonian signs [862–863](#)
functional inactivation in Huntington disease [865](#)
and infarction of posterior cerebral artery [1308](#)
lesions, and dyskinesias [864](#)
surgical intervention at in Parkinson disease [863](#) [863](#)

Subvocal rehearsal system, Broca's area [360](#)

Sulcal artery, spinal cord [1314](#)

Sulci [9](#) [324](#)
widened in schizophrenia [1195](#)

Sulcus limitans
neural tube [880](#)
relationship to cranial nerve nuclei [881](#)

Sulfation, of proteins in Golgi complex [96](#)

Summation
and action potential in central neuron [227](#)
columns, in primary auditory cortex [609](#)
spatial [223](#) [224](#)
temporal [222](#) [224](#)

Sunlight, and circadian rhythm [937](#)

Superior [321](#)

Superior and inferior colliculus [367](#)

Superior cerebellar artery [1303](#) [1304](#)

Superior cerebellar peduncle [833](#)

Superior cervical ganglion [964](#)
neuropeptides in [972](#)
in pupillary dilation [905](#)

Superior colliculus [482](#) [788](#)
control of saccadic eye movements [526–527](#)
cortical inputs [526](#)
cranial nerve nuclei at level of [884](#)
inhibited by basal ganglia [793](#)
lesions [793](#) [795](#)
movement signal to from frontal eye field [794–795](#)
movement-related neurons in [792](#)
projection of
optic nerve to [517](#)
retina to [523](#)
projections through thalamic pulvinar nucleus to cerebral cortex [526](#)
responses of neurons enhanced by selective attention [401](#)
retinal projections to [527](#)
role in eye movements [797](#)
rostral, and visual fixation [793](#) See *also* Tectum
structure [792](#)
and visual attention [565](#)
visuomotor integration of saccades [792–795](#)

Superior mesenteric ganglion [964](#)

Superior olivary complex, auditory pathway [606](#)

Superior olivary nuclei, auditory pathway [604](#)

Superior orbital fissure [877](#)
cranial nerves passing through [878](#)

Superior sacular ramus [802](#)

Superior salivatory nucleus, location and function [885](#)

Superior temporal cortex, lesions, effect on response to facial features [989](#)

Superior temporal gyrus [333](#)
damaged in global aphasia [1181](#)

Supplementary eye field, motor cortex [794](#)

Supplementary motor area [757](#) [760](#) [761](#)
damage after infarction of anterior cerebral artery [1308](#)
internally initiated movements [770](#)
language [1174](#)
left, damaged in transcortical motor aphasia [1180](#)
preparation of movement sequences from memory [773](#)
role in learning sequences of movements [771–774](#)

Supporting cell, olfactory epithelium [627](#)

Suppression columns, in primary auditory cortex [609](#)

Suppressor of hairless protein, transcription factor and neuronal cell fate [1043–1044](#)

Suprachiasmatic nucleus [976](#)
hypothalamus, control of circadian rhythm of sleep [45](#) [322](#) [946](#)
internal clock site in hypothalamus [937](#)
larger in homosexual than in heterosexual men [1145](#)

Supramarginal gyrus, language [1174](#)

Supraoptic nucleus [976](#)

Surface
reflectance curves [577](#)
reflectance function has component functions [578](#)

Surround [517](#)

Surround inhibition [463](#)
breakdown of in seizure focus [919-920](#)
loss of accompanies partial seizure [924](#)
seizure focus [921](#)

Survival, and drive states [999](#)

Substance P, neuroactive peptide [289](#)

Swaab, Dick [1145](#)

Sweat glands
control by sympathetic and parasympathetic system [968](#)
exocrine, establishment of neurotransmitter phenotype [1051-1052](#)

Sweet
tastant, mechanisms of transduction [639](#)
taste quality [637-639](#)

Swets, John [422](#)

Swimming, lamprey
pattern of muscle contractions in [745](#)
rhythmic locomotor pattern for [745](#)

Swing phase, stepping [740 741](#)

Sylvian fissure, of cerebral cortex [325](#)

Symbolic behavior [364](#)

Sympathetic neurons, establishment of neurotransmitter phenotype [1051-1052](#)

Sympathetic apraxia [355](#)

Sympathetic chain [963 964](#)

Sympathetic crisis [1221](#)

Sympathetic division, autonomic nervous system [961](#)
neurons and projections [964](#)

Sympathetic nerve trunk [962](#)

Sympathetic neuron
develops from neural crest cells [1047](#)
require neurotrophins for survival [1057](#)

P.1405

Sympathetic pathways [963](#)

Sympathetic preganglionic and postganglionic axons, anatomical organization [962](#)

Sympathetic system, autonomic division of peripheral nervous system [335](#)

Synaptic potential, in knee jerk [29](#)

Synapses [22 22 173 175](#)
action of membrane-permeable substances at [262](#)
central neuron, grouped according to function [223-226 225](#)
central nervous system, ultrastructure [1100](#)
in cerebral cortex [85](#)
chemical [173 175-177](#)
amplification of signals [182-185](#)
and electrical, functional properties [176](#)
excitatory actions at result from opening of channels permeable to be Na⁺ and K⁺ [210-211](#)
high density of voltage-gated Ca²⁺ channels [160](#)
nerve-muscle, signaling at [187-206](#)
neuromuscular [676](#)
plastic capabilities, role of regulation of free calcium concentration in presynaptic terminal [276](#)
plasticity of [34](#) See also Neurotransmitters
short-term versus long-term physiological changes [34](#)
synaptic delay [182](#)
synaptic transmission at, process [183](#)
transmission at [280](#)
current flow in chemical and electrical [176](#)
electrical [173 175-177](#)
depolarizing current generated by voltage-gated ion channels of presynaptic cell [177](#)
evidence for [178](#)
at gap-junction channels [177 178-179](#)
provide instantaneous signal transmission [177-182](#)
transmission is graded [178](#)
transmission of depolarizing and hyperpolarizing currents [178](#)
transmission of metabolic signals [180](#)
elimination of some after birth [1099 1100-1101](#)
en passant [85](#)
excitatory, distinctive ultrastructure [209-212](#)
formation
establishes information-processing circuit [1087](#)
in central nervous system similar to that at neuromuscular junction [1101-1104](#)
key steps [1087](#)
and regeneration [1087-1114](#)
formed by
motor neuron with muscle cells [78-79 81 85](#)
pyramidal cells in CA3 region of hippocampus on dendrites of CA1 cells in stratum radiatum [79](#)
selectivity of and target recognition molecules [1112](#)
inferring number of in reflex pathways [721](#)
inhibitory, distinctive ultrastructure [209-212](#)
location
on neuronal surface and function of cell [335](#)
in visceral motor system [962](#)
related to efficiency [227](#)
nerve-muscle, signaling at [187-206](#)
neuromuscular [676](#)
neuromuscular junction, substances organizing [1100](#)
primary nociceptive neurons with neurons of substantia gelatinosa of spinal cord [476](#)
rectifying [180](#)
those on axon terminals often modulatory [226](#)
those on cell bodies often inhibitory [224](#)
those on dendritic spines often excitatory [224-225](#)

Synapsin
binds vesicles to cytoskeleton [271 277](#)
proteins involved in neurotransmitter release [270](#)

Synaptic action, slow modulatory, release of neurotransmitters from dense-core vesicles [261](#)

Synaptic boutons [187](#)

motor neuron [73](#) [78](#)

Synaptic cleft [22](#) [23](#) [176](#) [182](#) [188](#)

central and neuromuscular synapses compared [1103–1104](#)

neuromuscular junction [189](#)

removal of

neurotransmitter terminates synaptic transmission [294–295](#)

neurotransmitters from [287](#)

Synaptic connections

changes in strength at and memory [1254](#)

effect of neurotrophins on survival [1124](#)

fine-tuning, and sensory experience [1115–1130](#)

growth

associated with activation of CREB-1 [1257](#)

and pruning, in consolidation of long-term implicit memory [1256–1257](#)

morphological types of in brain [209](#) [210](#) [212](#)

pruning of in long-term habituation [1257](#)

visual cortex, model for fine-tuning [1126–1127](#)

Synaptic current, reversal potential for [210–211](#)

Synaptic delay, calcium role in [277](#)

Synaptic excitation, comparison of that produced by opening and closing of ion channels [240](#)

Synaptic inhibition

associated with opening of K⁺ channels in cells with GABA receptors [217](#)

cerebral cortex [922](#)

control of spontaneously active nerve cells [209](#) [209](#)

short-circuiting effect [217](#)

shunting effect [217](#)

Synaptic input

influence properties of postsynaptic cell [1107](#)

neuronal response to [160](#)

Synaptic integration [207–228](#)

Synaptic mechanisms, underlying habituation [1249–1250](#)

Synaptic membranes, study with freeze-fracture technique [263](#)

Synaptic plasticity

associated with kindling [932–933](#)

fine-tuning [1277](#)

genetic control [1277](#)

molecular alphabet for [1272–1274](#)

NMDA-mediated, and spatial memory [1272](#)

Synaptic potential [29](#)

characteristics [31](#)

end-plate, method of production [190](#)

fast and slow in ganglionic transmission [970](#)

in knee jerk [29](#)

muscle, passive propagation [191](#)

originating in dendrites, and resistance [144](#)

quantal [257](#)

reversal potential for [210–211](#)

summation of as neuronal integration [222](#)

Synaptic receptors, types [229](#)

Synaptic regeneration, required for restoration of function after axon growth [1111–1112](#)

Synaptic stripping, after axotomy [1108](#)

Synaptic targets, specificity of axon recognition of [1105–1108](#)

Synaptic terminal

changes in membrane potential effect on intracellular calcium [274](#)

retraction, after axotomy [1109](#)

Synaptic transmission [173–310](#)

activity-dependent presynaptic depression of in habituation [1248–1250](#)

at chemical synapses, process [183](#)

P.1406

autonomic nervous system [962–963](#)

central nervous system [207–228](#)

changes in

effectiveness in short-term storage of implicit memory [1248–1254](#)

strength and learning [1250](#)

chemical [280](#)

genetically determined defects in depression [1224](#)

transmitting and receptive steps [183](#)

cholinergic [241](#)

abnormalities in narcoleptic dogs [951](#)

decrease in synaptic strength due to decrease of number of transmitter vesicles released from presynaptic terminals [1249](#)

effect of residual calcium [274](#)

electrical, demonstration in giant motor synapse of crayfish [177](#)

fast and slow in autonomic ganglion neurons [242](#)

long-lasting consequences endowed by second messengers [249–250](#)

long-term depression, cGMP cascade role in [240](#)

longest-lasting, changes in gene transcription [251](#)

mechanisms for [176](#)

modulation by second messengers [229–253](#)

monoaminergic, abnormalities in narcoleptic dogs [951](#)

overview [175–186](#)

presynaptic facilitation of in classical conditioning [1252](#)

sensitization [1250–1252](#)

process [182](#)

retrograde, evidence for [239](#)

return of organelle membranes involved in to cell body [97](#)

role of SNARE proteins [270](#)

second messengers in [230–231](#)

terminated by removal of neurotransmitter from synaptic cleft [294–295](#)

Synaptic vesicles [182](#) [188](#) [189](#)

- calcium mobilization [277](#)
- clear-core, in hair cells [622](#) [623](#)
- clustered at active zones [182](#)
- control of mobilization, docking, and function [272](#)
- discharge neurotransmitter by exocytosis [262–264](#)
- electron-translucent, in afferent terminals of nociceptive neurons [477](#)
- fusions [265](#)
- molecular machinery for fusion and exocytosis [273](#)
- neuron [68](#)
- neurotransmitter [31](#)
- neurotransmitter release from through opening of fusion pore [267](#)
- precursor membranes, anterograde transport to axon [101](#)
- proteins
 - involved in neurotransmitter release from [270–273](#)
 - and postulated receptors [271](#)
- recycling of [267](#) [269–270](#) [269](#)
 - by endocytosis [99](#)
- release small-molecule transmitters [295](#)
- store and release neurotransmitter [261–267](#)
- question of assembly [97](#)
- Synaptobrevin [271](#)
 - role in synaptic transmission [270](#)
- Synaptogenesis, highly interactive process [1112](#)
- Synaptophysin [271](#)
- Synaptotagmin [271](#)
 - isoforms [272–273](#)
 - membrane protein of synaptic vesicle [272](#)
- Syndactyly
 - cortical representation of hand after surgical correction [392](#)
 - use of to study cortical representation of hand [389–390](#)
- Sydenham, Thomas [1189](#)
- Syndrome [1189](#)
- Synergistic muscle [77](#)
- Syntactic processing, difficulties in Broca aphasia [1177](#)
- Syntactical processing [13](#)
- Syntax
 - grammar [1170](#)
 - principles of [1170–1171](#)
- Syntaxin [271](#)
 - role in synaptic transmission [270](#)
 - role in synaptic vesicle docking and fusion [277](#)
- Syringomyelia, cysts in spinal cord [733](#)

T

- t-SNARE proteins
 - docking and fusion of transport vesicles with target membranes [96](#)
 - role in synaptic vesicle docking and fusion [277](#)
- Tabes dorsalis [468](#)
 - and sensory neurons [33](#)
- Tabula rasa [411](#)
- Tachykinins, family of neuroactive peptides [290](#)
- Tacrine, treatment, Alzheimer disease [1158](#)
- Tactile information, object, fragmented by peripheral sensors and integrated by brain [452](#)
- Tactile stimulation
 - behavioral relevance modifies cortical response [468](#)
 - integration with visual stimuli in area 7 of posterior parietal cortex [465](#)
 - map of cortical responses to produced using evoked potentials [386](#)
- Tail-flip response, goldfish [180](#)
- Takahashi, Joseph [45](#)
- Talbot, Samuel [496](#)
- Tanji, Jun [764](#)
- Tanner, Wilson [422](#)
- Tanycytes [1293](#)
- Tanzi, Rudy [1157](#)
- Tardive dyskinesia [1201](#)
- Target cells, secrete neurotrophic factors [1055–1056](#)
- Target membrane SNARE proteins See t-SNARE proteins
- Target recognition molecules, selectivity of synapse formation [1112](#)
- Tastants [626](#)
 - interaction with taste cells [637](#)
 - sweet, binding to G protein-coupled receptors [638](#)
- Taste [625–647](#)
 - brain stem is site of entry for information from [320](#)
 - coding, nature of [644](#)
 - four different qualities of [637–642](#)
 - role of pons [322](#)
 - sensory cells [625–626](#)
 - sensory neurons for organized according to sensitivity [419](#)
 - types of stimuli [626](#)
- Taste buds [626](#)
 - detect taste stimuli [636–642](#)
 - innervation [637](#) [643](#)
 - taste cells in [638](#)
 - on tongue [636](#)
 - transmission of taste information to cerebral cortex [642](#)
 - types of cells in [636](#)
- Taste cells
 - clustered in taste buds [636–637](#)
 - ion channels in [637](#)
 - response to bitter tastant [640](#)
- Taste information

pathway [642](#)
related to cerebral cortex via thalamus [642–644](#)
transmission from taste buds to cerebral cortex [642](#)

Taste pore [637](#) [638](#)

Taste sensations, variations in patterns of activity in afferent fibers [644](#)

Taste stimuli
detected by taste buds [636–642](#)
detection [645](#)
mechanisms of transduction [639](#)
transduction [645](#)

Tau protein, Alzheimer disease [1154](#)

TDF See Testis determining factor

- neuroactive peptide [289](#)
- neurons releasing [979](#) [980](#)

Tight junctions, endothelial cells in brain microvessels [1290](#)

TIM protein

- circadian rhythm [44](#)
- light-dependent degradation and circadian rhythm in flies [46](#)

Time constant, passive membrane property of neuron [222](#)

Timed response paradigm, parallel processing in movement [664](#) [665](#)

timeless gene, *Drosophila*, role in circadian rhythm [42](#) [44](#)

Timing

- role of cerebocerebellum [846](#)
- stimulus attribute conveyed by sensory system [412](#) [414](#) [413](#)

Tinel sign [703](#)

Tinnitus [807](#)

Tip link, hair cells [615](#) [617](#)

Tissue injury, major ascending pathways for information [480-482](#)

TMA See Tetramethylammonium

Todd paralysis [922](#)

Tolerance

- drug [1011](#)
- opioid peptides [489](#)

Tolman, Edward [382](#)

Tonegawa, Susumi [1266](#)

Tongue

- spatial segregation in nucleus of solitary tract, thalamus, and cortex [644](#)
- taste information pathway [642](#)
- types of papillae on [636](#) [637](#)

Tonic neurons [790](#)

Tonic phase, partial seizure [913](#)

Tonic-clonic seizure [913](#)

- neuronal activity during [922](#)

Tononi, Giulio [1318](#)

Tonotopic mapping, hair cells [620](#)

Tonotopic map

- on basilar membrane [594](#)
- formation of on neurons in cochlear nucleus, inferior colliculus, and auditory cortex [1127](#)
- in primary auditory cortex [609](#)

Tonsil, cerebellum [833](#)

Top of the basilar syndrome, bilateral brain stem lesions [1312-1313](#)

Topognosis [431](#)

Topographic map

- body surface, in each of four Brodmann regions of somatic sensory cortex [458](#)
- in brain [323](#)
- internal organ system, in anterior insular cortex [974](#)
- retinal, generated by synchronous activity [1127](#) See also Retinotopic map

Topographic representation, axons of retinal ganglion cells at termination in optic tectum [1064](#)

Torque, muscle [688](#)

tottering mouse mutant, model for study of primary generalized seizures [925](#) [930](#)

Touch [451-471](#)

- dorsal column-medial lemniscal system is pathway for perception [447-448](#)
- information about integrated by primary somatic sensory cortex [452-458](#)
- mediated by

 - dorsal root ganglion neurons with encapsulated peripheral terminals [431](#)
 - mechanoreceptors in skin [432-441](#)

- model for principles of cortical organization that give rise to conscious perception [451](#)
- path of information for [341](#)
- structural basis of receptive field of receptors for [419](#)
- study of to explore internal representations of personal space [384](#)

Tourette syndrome, and basal ganglia [1224](#)

Tower of Hanoi, test of frontal lobe function [358](#)

Tower of London task, test of frontal lobe function [358](#)

Toxins

- as blocking molecules in ion channels [112](#)
- effect on functional state of ion channels [115](#)
- ion channels as site of activity [105](#)

Tract of Lissauer [448](#)

Training

- effect on functional organization of primary motor cortex [761-763](#)
- expansion of existing representation of fingers in cortex [1274](#)
- and increased representation of movement in primary motor cortex [763](#)
- massed and spaced [1250](#)

P.1409

- repeated, conversion of short-term into long-term memory [1254](#)

trans -(1S, 3R)-1-amino-1, 3-cyclopentanedicarboxylic acid, activates metabotropic glutamate receptors [212](#)

Trans-Golgi network [96](#)

Transcortical motor aphasia

- brain areas damaged in [1180](#)
- characteristics [1176](#)
- nonfluent speech in [1180](#)

Transcortical responses [767](#)

Transcortical sensory aphasia

- brain areas damaged in [1180](#)
- characteristics [1176](#)

Transcortical sensory area, fluent speech with impaired comprehension in [1180](#)

Transcription, DNA conversion to mRNA [88–89](#)

Transcription factors

- regulatory DNA-binding proteins [88–89](#) See also C/EBP; CREB
- segmental expression in hindbrain patterning [1033](#)
- Sox gene family, neural plate cell differentiation [1026](#)

Transcutaneous electrical stimulation, relief of pain [482](#)

Transducin, inactivation terminates light response in phototransduction [514](#)

Transfer RNA, mitochondrial [89](#)

Transformation, signal in stretch reflex pathway [32–33](#)

Transforming growth factor beta, neural crest cell fate [1047](#)

Transgenes

- expression, methods of regulating [1268–1270](#) [1269–1270](#)
- introducing in flies and mice [43](#)
- methods for turning on and off [1268](#)

Translation, messenger RNA [90–91](#)

Translational vestibulo-ocular reflex [809](#)

Transmembrane proteins

- cone photopigments [576](#)
- GABA receptor [219](#)
- glutamate receptor [219](#)
- glycine receptor [219](#)
- method of formation in endoplasmic reticulum [95](#) See also Receptors

Transmission

- directly gated, at nerve-muscle synapse [187–206](#)
- electrical, rapid and synchronous firing of interconnected cells [180](#)
- synaptic, process [182](#)

Transmitters [173](#)

- act through second messengers to stimulate local protein synthesis in specific dendritic spines of postsynaptic neurons [250](#)
- action through second messengers to mediate phosphorylation of transcriptional proteins [249–250](#)
- chemical [31–32](#)
- chemical
 - common biochemical features of receptors for [185](#)
 - short- and long-term effects on ion channels [250](#)
- release triggered by calcium influx at presynaptic nerve terminals [160](#) See also Neurotransmitters

Transneuronal degeneration, after axotomy [1109](#)

Transneuronal degeneration, after axotomy [1109](#)

Transport systems, carrier-mediated, and blood-brain barrier [1290–1292](#)

Transport vesicles

- docking and fusion with target membranes [96](#)
- for export of proteins [96–97](#)
- neuron [68](#) [69](#)

Transporters

- chloride [132](#)
- ion conductance across cell membranes [108](#)
- reuptake of transmitter substance [294–295](#)
- types [295](#)
- vesicle, for concentrating neurotransmitters [285–286](#)

Transposable elements [48](#)

Transsexualism [1143](#)

Transverse tubules, muscle fiber [677](#)

Trapezoid body, auditory pathway [604](#) [606](#)

- cranial nerve nuclei at level of [884](#)

Treisman, Anne [502](#) [504](#) [566](#)

trembler mutation, mouse, identification of peripheral myelin protein [22](#) [83](#)

Tremor, cerebellar abnormality [849](#)

Trial-and-error learning See Operant conditioning

Tricyclic antidepressants

- block uptake of serotonin [295](#)
- treatment
 - cataplexy [951](#)
 - panic attacks [1221](#)
- effect on serotonergic and noradrenergic neurons [1218–1219](#)

Tricyclic compounds, antidepressants [1214](#)

Trifluopromazine, structure [1198](#)

Trigeminal cranial nerve (V)

- function and dysfunction [874–875](#) [877](#)
- lesion [878](#)
- motor and sensory roots [877](#)
- origin at brain stem [876](#) [877](#)

Trigeminal lemniscus, ascending somatosensory pathway [448](#)

Trigeminal motor nuclei [671](#)

Trigeminal motor nucleus [881](#)

- location and function [883](#)

Trigeminal nerve

- areas of innervation [880](#)
- in developing hindbrain [1031](#)
- mesencephalic nucleus of, control of sleep [941](#)

Trigger component

- generation of action potential [29–30](#)
- nerve cell signaling [29–30](#)

Trigger signal [27](#)

Trigger zone [30](#) [30](#) [223](#)

- high density of voltage-gated Na⁺ channels [160](#)
- motor neuron [78](#)

Trinucleotide amplification, myotonic muscular dystrophy [710](#)

Trinucleotide expansion

- and genetic anticipation [54](#)
- role in Huntington disease [54](#)

Trinucleotide repeats

- in huntingtin gene for Huntington disease [865](#)
- neurological diseases involving [55](#)
- types involved in neurological diseases [56](#)

Trinucleotide repeat diseases [704](#)
Triplet repeat diseases [704](#)
Tritanopia [584](#)
trkA, B, and C, neurotrophic receptors [1056](#) [1057](#)
trkB receptors, interference with blocks formation of ocular dominance columns [1124](#)
Trochlear cranial nerve (IV)
function and dysfunction [874-875](#) [877](#)
origin at brain stem [876](#) [877](#)
Trochlear nerve
in developing hindbrain [1031](#)
innervation of extraocular muscle [787](#)
lesion [788](#)
Trochlear nuclei, location [883](#)
Trochlear nucleus [881](#)
Tropism [1080](#)
Tropomyosin
in muscle fibers [677](#) [678](#)
muscle contraction [679](#)
Troponin, in muscle fibers [677](#) [678](#)
Trunk
motor control and sensation mediated by spinal cord [320](#)
somatosensory information conveyed from by dorsal root ganglion neurons [431](#)
from carried to spinal cord [338-340](#)
Tsien, Joe [1266](#)
TTX See Tetrodotoxin
Tuber, cerebellum [833](#)
Tuberculoventral cell, cochlear nucleus [605](#)
Tuberoinfundibular hypothalamic neuroendocrine system, dopaminergic neurons in [893](#)
P.1410
Tuberomammillary nucleus
in ascending arousal system [900](#)
histaminergic neurons in [894](#) [895](#) [896](#)
hypothalamus [977](#)
Tubulin, in microtubules [72](#)
Tufted relay cells, olfactory bulb [630](#) [631](#)
Tully, Tim [1259](#)
Tulving, Endel [1231](#)
Tumors
affecting cranial nerves [877](#)
brain, and blood-brain barrier function [1294](#)
Tuning curve, frequency sensitivity of hair cell [599](#) [599](#)
Twin studies
anatomical abnormalities in brain in schizophrenia [1195-1196](#)
for evaluating role of genes and environment in complex behavior [40-42](#) [41](#)
homosexuality [1145-1146](#) [1145](#)
personality [42](#)
schizophrenia [1193-1194](#)
Twins
monozygotic
versus dizygotic [40](#)
concordance rate for bipolar depression [1212](#)
enlargement of lateral ventricle in schizophrenia [1197](#)
sleep patterns in [944](#)
Twitch contraction [681](#)
Two-point discrimination
and lateral inhibition [461](#)
skin [464](#)
Two-point threshold [438](#)
Tympanic membrane [595](#)
Tympanum [591](#) [591](#) [595](#)
Tyrosine kinase
ACh receptor as substrate for [248](#)
regulation [235](#)
dimerization [239](#)
membrane-spanning, as neurotrophic receptors [1056](#)
nonreceptor [230](#)
pathway, receptor and cytoplasmic kinases in [238-239](#)

U

Ubiquitin, addition of as post-translational protein modification [90](#) [93](#)
Ubiquitin carboxyterminal hydrolase, in long-term facilitation [1254-1257](#)
Umami, taste quality [642](#)
Unconditioned response [1240](#)
Unconditioned stimulus [1240](#)
Ungerleider, Leslie [500](#) [1237](#)
Unimodal association areas [350](#)
cerebral cortex [345](#)
Unimodal association cortex, processing of sensory information in cerebral cortex [345](#)
Unipolar disease See Depression, unipolar
Unreality, ictal phenomenon [15](#)
Unwin, Nigel [199](#)
Upper contralateral quadrantic anosia [544](#)
Upper motor neurons [696](#)
symptoms of disorders of [696](#)
Urbach-Wiethe disease, amygdala [988-989](#)
Urogenital reflexes, mechanism [968-969](#)
Utricle [802](#)
axis of mechanical sensitivity [805](#)
cochlea [592](#)
detection of linear acceleration [804-805](#)
reports linear accelerations [802](#)

structure [804](#)
Uvula, cerebellum [833](#)

V

V See Potential difference
 V_m see Membrane potential
V-SNARE proteins, docking and fusion of transport vesicles with target membranes [96](#)
V1 See Primary visual cortex
V2, visual cortex
 cells in respond to both illusory and actual contours [562–563](#)
 higher-level information processing of illusions of edges [564](#)
 interconnections with V1 [549](#)
 organization [549](#) See also Secondary visual cortex stripes and interstripes in, [550](#)
V4, visual cortex
 analyzes and represents color information in image [583](#)
 cells in respond to form [563–564](#)
 color-opponent neurons in [588](#)
 effects of visual attention on cells of [565–566](#)
 neurons, response to effective visual stimulus modified by selective attention [568](#)
 secondary visual area projects to [583](#)
Vacuolar apparatus proteins
 manufacture on rough endoplasmic reticulum [103](#)
 synthesized and modified in endoplasmic reticulum [94–96](#)
Vacuolar apparatus
 neuron [69](#)
 role in protein synthesis [91](#)
Vagal nucleus, dorsal, preganglionic parasympathetic nucleus in brain stem, projections [963](#)
Vagus cranial nerve (X)
 function and dysfunction [874–875](#) [879–880](#)
 injury [880](#)
 origin at brain stem [876](#) [877](#)
Vagus nerve
 in developing hindbrain [1031](#)
 and homeostasis [965](#)
Vagusstoff [966](#)
Valium
 effect on gating of ion channels in response to GAB A [114](#) [116](#) See Benzodiazepines
Vallbo, Ake [729](#)
Valproic acid, blocks absence seizures [924](#)
VAMP
 in synaptic transmission [270](#)
 in synaptic vesicle docking and fusion [277](#)
Van Essen, David [496](#)
Vannilloid receptor, in nociceptors [474](#)
Varicosities [962](#)
Vascular lesions
 brain stem, syndromes [1310](#) See also Infarction; Occlusion
Vascular syndromes, brain stem [1312](#)
Vascular volume, regulation of drinking [1006–1007](#)
Vasoactive intestinal peptide, co-release with ACh [290](#)
Vasoactive intestinal polypeptide [972](#)
 neuroactive peptide [289](#)
Vasogenic edema [1294](#)
 brain [1299](#)
Vasopressin
 magnocellular endocrine neurons [987](#)
 neuroactive peptide [289](#)
 posterior pituitary gland [979](#)
 transmitter in neurons innervating antipyretic area of brain [1002](#)
 secretion by hypothalamic magnocellular neurons [979](#)
Vegetative state, persistent, as result of bilateral forebrain damage [900](#) [901](#)
Venterolateral nucleus [761](#)
Ventral amygdalofugal pathway [987](#)
Ventral columns, white matter of spinal cord [338](#) [338](#)
Ventral corticospinal tract, pathway [670](#)
Ventral horn, spinal cord [319](#) [338](#)
Ventral occipital cortex, localized damage to causes loss of color vision [563–564](#)
Ventral posterior and ventral medial nuclei, pathway of sensory information [446](#)
Ventral posterior lateral nucleus [342](#)
 thalamic [482](#)
Ventral posterolateral nucleus [761](#)
Ventral premotor area, individual cell active if monkey performs task or observes task being performed [777](#)
Ventral root, spinal cord [320](#)
Ventral striatum, basal ganglia [855](#)

P.1411

Ventral sulcus, spinal cord [338](#)
Ventral tegmental area, dopaminergic neurons in [896](#)
Ventral [321](#)
Ventricle [325](#) [332](#)
 lateral and third, enlarged in schizophrenia [1195](#) [1196](#) [1197](#)
 third [369](#)
Ventrrolateral funiculus [751](#)
Ventrrolateral medulla
 in autonomic response control pathway [975](#)
 pathway of visceral sensory information [974](#)
Ventrrolateral medullary reticular formation [885](#)
Ventrrolateral nucleus, thalamus [347](#)
Ventromedial hypothalamic nucleus [976](#)
Ventromedial motor nucleus [668](#)
Ventromedial nucleus, hypothalamus [977](#)
Ventroposterior parvocellular nucleus, projections to [973–974](#)

Verbal tasks, sex differences [1142](#)

Vergence [797](#)

- movement system, eye [783](#) [785](#)
- organized in midbrain [796](#)

Vermis, cerebellum [833](#) [834](#)

- lesions of [850](#)

Vertebral artery [1303](#)

- branches supply blood to brain stem and cerebellum [1309](#)
- infarction, brain stem syndromes produced [1311-1312](#)

Vertigo, cerebellar infarction [1313](#)

Vesicles

- anterograde transport to axon [101](#)
- classes of [97](#)
- clathrin-coated, in endocytic traffic [98](#)
- coated, in exocytosis [265](#)
- concentrations of neurotransmitters in [285](#)
- dense-core
 - contain neuropeptides and small-molecule neurotransmitters [281](#)
 - store neuropeptides and neurotransmitters [261](#)
- large dense-core
 - in afferent terminals of nociceptive neurons [477](#)
 - anterograde transport to axon [101](#)
 - storage of neuropeptides [290](#)
 - store peptide neurohormones [97](#)
 - targeted to axons [97](#)
- neurotransmitter, and quantal synaptic potential [277](#)
- package chemical messengers [296](#)
- precursors, neuron [68](#)
- secretion of proteins from Golgi complex [97](#)
- small lucent, contain small molecule neurotransmitters [281](#)
- SNARES, role in synaptic transmission [270](#)
- synaptic, question of assembly [97](#)
- transport, for export of proteins [96-97](#)
- transporters [287](#)
 - for concentrating neurotransmitters [285-286](#)

Vesicular SNARE proteins See v-SNARE proteins

Vesicular-ATPase, vesicle transporter [285-286](#)

Vestibular apparatus

- habituation [809-810](#)
- integration of vestibular, visual, and motor signals [810-813](#)

Vestibular canals, disease in, nystagmus [812](#)

Vestibular ganglia of Scarpa [802](#)

Vestibular ganglion [803](#)

Vestibular labyrinth [802](#)

- defects in, and loss of balance [824](#)
- effect of removal in cat [825](#)
- Meniere disease [807-808](#)
- parallel fiber input to Purkinje cells [827](#) [828](#)
- Purkinje cells' inhibitory influence on vestibular nuclei [825](#) [828](#)
- receptor organs [802-808](#)

Vestibular movements, eye [797](#)

Vestibular nerve [591](#) [801](#) [803](#) [807](#) [808](#)

- anatomical connections [812](#)
- cochlea [592](#)
- signals head velocity to vestibular nuclei [810-812](#)

Vestibular nuclei [801](#)

- afferent inputs [810](#)
- lateral and medial [669](#)
- location and function [882](#)
- medial and lateral, inhibitory effect of Purkinje neurons on [841](#)
- optokinetic and vestibular peripheral inputs to [828](#) [829](#)
- projections to oculomotor system [814](#)
- receive signals regarding head velocity from vestibular nerve [810-812](#)
- vestibulo-ocular reflex [811](#) [811](#) [812](#)

Vestibular nucleus [808](#) [881](#)

- ventral corticospinal tract [670](#)

Vestibular nystagmus [809](#)

- resets eye position during sustained rotation of head [809](#)

Vestibular projection, cerebral cortex, perception of rotation and vertical orientation [813](#)

Vestibular receptors, lesions, cause disorientation and vertigo [807](#)

Vestibular reflexes

- stabilize eyes and body when head moves [808-810](#)
- volitional control [822-823](#)

Vestibular schwannoma, vestibulocochlear cranial nerve [879](#)

Vestibular signals, convergence with vestibular signals during rotational movements [828-829](#)

Vestibular system [801-815](#)

- contributions to postural control [821-824](#) [824](#)
- projects information in top-down manner [830](#)

Vestibulocerebellum [834](#)

- inputs and projections [840](#)
- regulates balance and eye movements [841](#)

Vestibulocochlear cranial nerve (VIII)

- function and dysfunction [874-875](#)
- functions [879](#)
- origin at brain stem [876](#) [877](#)

Vestibulocochlear nerve [807](#)

Vestibulocollic reflex, stabilizes head relative to space [822](#)

Vestibulo-ocular control

- motor learning in [824-828](#)
- role of cerebellum in adaptation [825-828](#)

Vestibulo-ocular eye movements [783](#)

Vestibulo-ocular reflex [808](#)

- adaptive learning, memory of in brain stem [828](#)
- compensate for head movement [808-809](#)
- effect of
 - magnifying lenses [825](#) [826](#)
 - prism glasses on [848](#)
- horizontal [812](#)
- hypotheses of adaptive adjustment [826-827](#)
- supplemented by optokinetic system [809-810](#)
- types [809](#)
- Vestibulo-ocular system [783](#)
- Vestibulospinal reflexes [808](#)
 - collaboration with cervicospinal reflexes to maintain postural stability [823-824](#) [823](#)
 - maintain vertical posture [810](#)
- Vestibulospinal tracts [669](#)
 - medial brain stem pathway [668](#)
- Vibration sense, coded by spike trains in mechanoreceptors in skin [437](#)
- Vibrissae [462](#)
- Video microscopy techniques [101](#)
- Vigilance
 - increased by ascending monoaminergic projections from brain stem and hypothalamus [896-897](#)
 - role of locus ceruleus [896](#)
- Vilis, Tutiis [844](#)
- Vincent, Angela [306](#)
- Violence See Behavior, aggressive
- VIP See Vasoactive intestinal peptide
- Virchow, Rudolf [1189](#)
- Virchow-Robin spaces, blood vessels in subarachnoid space [1296](#)
- Viscera
 - innervated by dorsal root ganglion neurons [444](#)

P.1412

- mechanosensory and chemosensory receptors in [443-444](#)
- signals from nociceptors in and pain elsewhere in body [475](#)
- Visceral function, role of hypothalamus [8](#)
- Visceral motor cortex [974](#)
- Visceral motor nuclei, in developing hindbrain [1031](#)
- Visceral motor system
 - reflex circuits in [962](#)
 - synapses in [962](#)
- Visceral reflexes, and autonomic nervous system [961](#)
- Visceral sensory afferents [980](#)
- Visceral sensory information, pathways [973-974](#) [974](#)
- Visceral sensory thalamus, projections to [973](#)
- Visible spectrum [574](#)
- Vision
 - achromatic [579](#)
 - color [572-589](#)
 - depth, monocular cues and binocular disparity [558-562](#)
 - disturbed, diffuse hypoperfusion [1313](#)
 - guidance of movement [654](#)
 - independence from language [364-365](#)
 - object versus stereopsis [561-562](#)
 - role of
 - occipital lobe [9](#)
 - posterior nuclei of thalamus [343](#) See also Depth; Form; Gaze; Motion; Object vision
 - stereoscopic [560](#)
 - neuronal basis [561](#)
 - vestibular stabilization of eye relative to space [828-829](#)
- visuospatial sketch pad for in working memory [1239](#)
- Visual area 1 See Primary visual cortex
- Visual attention See Attention, visual
- Visual cortex
 - cells responsive to binocular disparity [561](#)
 - function MRI study [374](#)
 - hierarchical pathways in two cortical pathways [552](#)
 - information conveyed by magnocellular and parvocellular pathways [529-532](#)
 - model for fine-tuning of synaptic connections [1126-1127](#)
 - monkey, different disparity profiles in neurons [562](#)
 - partial lesions, partial visual deficits on opposite side [544](#)
 - projections to [1116](#) See also Primary visual cortex; V2; V4
 - serial pathways through [552](#)
 - transformation of visual signals [581-583](#)
- Visual deprivation See Eye closure
- Visual field [524](#)
 - binocular and monocular zones [524](#)
 - correspondence of regions with retinal image [525](#)
 - decomposition into short line segments [545](#)
 - deficits in produced by lesions at various points in visual pathway [544](#)
 - each half represented in contralateral primary visual cortex [532](#)
 - gaps in associated with lesions in retino-geniculate-cortical pathway [543-545](#)
 - one region of, hypercolumn representation of visual properties of [539-540](#)
 - optic flow [553](#)
 - perception of motion in [551](#)
 - retinal image inversion of [524-525](#) [526](#)
 - visual information [504](#)
- Visual hemifield, left and right [525](#)
- Visual image
 - background versus foreground [497](#)
 - built up from inputs of parallel pathways [502-504](#)
 - construction [492-506](#)
 - contrasts and rapid changes detected by ganglion cells [519-520](#)
 - ganglion cells process different aspects [520](#)

and interactions among areas of cerebral cortex [505](#)
outlines of decomposed into short line segments in primary visual cortex [533-535](#)
primary visual cortex organizes retinal inputs into building blocks of [532-537](#)
receptive field of each receptor [420](#)
requirement of focused attention on elements in visual field [502](#)

Visual information

areas of cerebral cortex dedicated to [499](#)
carried by brightness variations [579](#)
combination into coherent image, hypothetical model [504](#)
and motor systems, role of parietal neurons [567](#)
parallel pathways [500-501](#) [517](#)
processing in
cerebral cortex, PET measurement of local blood flow changes during [378](#)
multiple cortical areas [496-497](#)
selective filtering by visual attention [565](#)
subcortical processing by lateral geniculate nucleus [529](#)

Visual neglect [498](#)

Visual neurons, in frontal eye field [794](#)

Visual orientation, disrupted by lesions in parietal cortex [498](#)

Visual pathways

central [523-547](#)
early transformation of cone signals [577-581](#)
functions mediated by [502](#)
P and M [501](#)

Visual perception

activity of extrastriate cortex [500](#)
development of [1116-1117](#)
focal attention [503](#)
frames of reference [498](#)
preattentive scanning [503](#)
requires sensory experience [1115-1117](#)
and selective attention [400](#)
sequential processes [502-503](#)
winner-take-all perceptual strategy [494](#)

Visual pigments

absorption of light by in photoreceptors [510](#)
in cones [512](#)
genes encoding are on X chromosomes [584-585](#)

Visual processing

and developmental dyslexia [1185](#)
by retina [507-522](#)

Visual signals, transformation in visual cortex [581-583](#)

Visual space, representation of body related to [402](#)

Visual spatial agnosia [500](#)

Visual stimuli

development and role of orientation columns [1125](#)
integration with tactile stimuli in area 7 of posterior parietal cortex [465](#)
responses of neurons in area 17 of monkey visual cortex [1117](#)

Visual system [492-506](#)

anatomical pathways [496-197](#)
binding problem [492](#) [566-567](#)
circuits refined by sensory experience [1115](#)
cognitive function [492](#)
components of in midbrain [322](#)
confusion by artificial means [577](#)
distributed processing [496](#) [505](#)
M and P pathways [581](#)
magnocellular pathway, slower conduction in people with dyslexia [1185](#)
molecular cues for development [1115](#)
motion information processed in two stages [554](#) [556](#)
parallel pathways in [504-505](#) [521](#) [545](#) [567-568](#)
on-center and off-center ganglion cells [519-520](#)

P.1413

receptive field of sensory neurons defines spatial resolution of stimulus [418-419](#)
separate circuits for global versus local features of object [397](#)
serial pathway [505](#)
structure [1116](#)

Visuomotor integrator, superior colliculus [792-795](#)

Visuomovement neurons, in frontal eye field [794](#)

Visuospatial buffer, localization [360](#)

Visuospatial sketch pad

localization [360](#)
working memory [1239](#)

Visuospatial tasks, sex differences [1142](#)

Vitamin A, deficiency, night blindness [512](#)

Vitamin B12 deficiency, chronic neuropathy [702](#)

V_m See Resting membrane potential

Vogt, Marthe [299](#)

Volition, disorders of, schizophrenia [1188-1208](#)

Voltage

current in ion channel related to linearly [109-110](#) [110](#)
equal to membrane potential [143](#)
relationship with current [141](#)

Voltage clamp technique [169](#)

calculate membrane conductance [155](#)
current generator [152](#)
determining origin of electrical resonance in hair cells [621](#)
demonstrates rapid rate of Na^+ channels turning on and off over range of membrane potentials [156](#)
determine separate time courses of oppositely directed currents [153](#)
electrical equivalent circuit of nerve cell undergoing [155](#)
mechanism of [151](#) [152](#)

negative feedback system [152](#)
study of end-plate potential [190](#) See *also* Patch-clamp technique, 152
study of Na⁺ and K⁺ conductance as function of membrane potential [151](#)
study of Na⁺ and K⁺ currents with [151-154](#)
Voltage response, passive neuronal process, and electrotonic conduction [145](#)
Voltage-gated channel, structure [119](#) [118](#) See Ion channel, voltage-gated
Voltametry [266](#)
Voluntary behavior, law of effect [1242](#)
Voluntary movement [756-781](#) See *also* Movement, voluntary
Vomeronasal organ
 mediates information about pheromones [634](#)
 olfactory information processing [633](#)
 pattern of expression of pheromone receptors [635](#) [635](#)
 sensory transduction in [634](#)
Vomeronasal receptors, layered [634](#)
Vomeronasal system [634](#)
 von Bekesy, Georg [594](#)
 von Helmholtz, Herrmann [6](#)

W

Wada test, for hemispheric distinction [364](#)
Wagnor, Jackson [1134](#)
Wake-sleep cycle
 with no cognitive content, as persistent vegetative state [900](#)
 role of serotonergic neurons [896](#)
Wakefulness
 disorders of [948-959](#)
 increased by ascending monoaminergic projections from brain stem and hypothalamus [896-897](#)
Waking, signaling activity of thalamic relay neurons [899](#)
Waking state, promoted by stimulation of midbrain reticular formation [939](#)
Walker, Mary [299](#)
Walking
 central motor command for modifies transmission in spinal reflex pathways [724](#)
 human
 bipedal and demands on descending systems [754](#)
 spinal pattern generators in [753-754](#)
 proprioceptive signals in [727](#)
 role of descending pathways in initiation and adaptive control [750-753](#) [750](#) See *also* Locomotion; Stepping
 spinal circuits in [717](#)
Wallenberg syndrome, damage of cranial nuclei in lateral medulla [886](#) [886](#)
Wallenberg, Adolph [886](#)
Waller, Augustus [88](#)
Wallerian degeneration, after axotomy [1108](#) [1109](#)
Warm-sensitive neurons, hypothalamus [1001](#)
Warmth, mediated by thermal receptors [444-445](#)
Warrington, Elizabeth [1237](#)
Water, shell of surrounding ions [108](#)
Water balance, regulation by hypothalamus [1006-1007](#)
Water intake, set point [1006](#)
Water maze
 memory test [1267](#) [1271](#) [1272](#)
 test of spatial memory defects [1271](#)
Water regulation, feedback signals for [1006](#) See *also* Drinking
Water-soluble compounds, transport across blood-brain barrier [1292](#)
Watson, J.B. [382](#)
Weakness
 after occlusion of carotid artery [1309](#)
 areas of after middle cerebral artery infarction [1307-1308](#)
 infarcts of medial or lateral brain stem structures [1311](#)
Weber syndrome, midbrain infarction [1312](#)
Weber's law [421](#)
Weber, Ernst [411](#) [412](#) [421](#)
Weigert stain, layers of neurons in cerebral cortex [326](#)
Weinberg, Stephen [398](#)
Weinberger, Daniel [1203](#)
Weischaus, Eric [1032](#)
Weiskrantz, Lawrence [1318](#)
Weiss, Paul [100](#) [1064](#)
Wender, Paul [1193](#) [1212](#)
Werner syndrome, premature aging, mechanism [1150](#)
Wernicke aphasia
 after middle cerebral artery infarction [1308](#)
 characteristics [1176](#)
 damage to left temporal lobe structures [1179-1180](#)
MRI of lesion [1179](#)
 phonemic paraphasias in [1179-1180](#)
 spontaneous speech, auditory comprehension, and repetition in [1178](#)
Wernicke's area
 activation when words are heard [13](#)
 language [1174](#) [1175](#)
 lesion, effect on speech [897](#)
 and speech [11](#)
 temporal lobe, damage to produces sensory aphasia [355](#)
Wernicke, Karl [7](#) [10-11](#)
Wernicke-Geschwind model, language [1175](#)
Wertheimer, Max [493](#)
Wheatstone, Charles [560](#)
Whiskers
 and developmental organization of barrels in somatosensory cortex of rodents [1037](#) [1037](#)
 mapping in primary motor cortex and plasticity [761](#)
 representation on rodent cortex [460](#) [462](#) See *also* Barrels

White communicating ramus [962](#)
White matter, spinal cord [319](#)
 structure [338](#)
White myelinated rami [963](#)
Wide-dynamic-range neurons, in dorsal horn of spinal cord [475](#)
Wiesel, Torsten [529](#) [533](#) [537](#) [579](#) [1116](#)
Wilks, Samuel [299](#)
Williams syndrome [1172](#)
Wind-up phenomenon, C fibers [479](#)
Winner-take-all perceptual strategy, visual perception [494](#)

P.1414

Wisconsin Card Sorting Test
 blood flow to prefrontal areas in schizophrenic patients [362](#)
 test of frontal lobe function [358](#)
Withdrawal reflexes, muscle [654](#)
Wnt-1, differentiation of mesencephalon [1034](#)
Wolffian ducts, sexual differentiation [1133](#) [1133](#)
Woodworth, Robert [662](#)
Woolsey, Clinton [385](#)

Word [1170](#)

Words

 activation of different areas of cerebral cortex [13](#)
 PET identification [14](#)
 association, role of cerebellum [848](#)
 for categories of things, left temporal cortices contain neural systems for accessing [1182](#)
 open-class and closed-class vocabularies [1170](#)
 recall of in amnesiacs and normal subjects [1230](#)

Working memory [357](#)

 and Broca aphasia [1179](#)
 components [357](#)
 cortex surrounding the principal sulcus [357-361](#)
 imaging of [360](#)
 modular nature [359](#)
 nonverbal [360](#)
 and prefrontal association area [357](#) *See also* Memory
 tracked by neurons in principal sulcus [361](#)
 verbal [360](#)

Worm *See* *Caenorhabditis elegans*

Writing

 acquired disorders of [1183-1184](#)
 motor equivalence in [657](#)
 versus language [1170](#)

Wundt, Wilhelm [411](#) [1317](#)

Wurtz, Robert [400](#) [565](#)

X

X chromosome

 L and M pigment genes on [585](#)
 locus of genes encoding visual pigments [584-585](#) *See also* Duchenne muscle dystrophy; Mental retardation

X-linked spinal and bulbar muscular atrophy, trinucleotide repeats in [55](#)

X-ray computerized tomography, functional imaging of brain [366](#)

X-ray crystallography

 structure of extracellular glutamate binding domain [220](#)
 study of ion channels [109](#)
 used to solve structure of K⁺-selective ion channels [120-123](#) [122](#)

X-ray diffraction studies, three-dimensional structure of gap-junction channel [179](#)

XX individual, formation, phenotypic female [1132](#) [1132](#)

XX male, formaton [1132](#) [1132](#)

XY female, formation [1132](#) [1132](#)

XY individual, formation, phenotypic male [1132](#) [1132](#)

Y

Y chromosome

 location of testis determining factor [1132](#)
 in sex determination [1132](#)

Yellow-blue mechanism, in cones [580](#)

Yellow-blue variation, component function of reflectance function [578](#)

Yeo, Christopher [849](#)

Yin, Jerry [1259](#)

Yohimbine

 induces panic attack in patients with post-traumatic stress disorder [1222](#)
 induction of panic attacks [1221](#)

Young, Thomas [575](#)

Z

Z disk, sarcomere [677](#) [678](#)

Zeitgebers, timing cues [937](#)

Zeki, Semir [496](#) [505](#) [583](#) [587](#)
